TRANSACTIONS

OF THE

AMERICAN SOCIETY

OF

CIVIL ENGINEERS

(INSTITUTED 1852)

VOL. LXXXVI

1923

Edited by the Secretary, under the direction of the Committee on
Technical Activities and Publications.

Reprints from this publication, which is copyrighted, may be made on condition that the full title of Paper, name of Author, and page reference are given.

NEW YORK
PUBLISHED BY THE SOCIETY

1923

Entered according to Act of Congress, in the year 1923, by the AMERICAN SOCIETY OF CIVIL ENGINEERS, in the Office of the Librarian of Congress at Washington.

NOTE.—This Society is not responsible for any statement made or opinion expressed in its publications.

CONTENTS

PAPERS

No.		PAGE
1509	**ENGINEERING GEOLOGY OF THE CATSKILL WATER SUPPLY.**	
	By **Charles P. Berkey and James F. Sanborn**	1
	Discussion:	
	By ALFRED D. FLINN	68
	GEORGE G HONNESS	69
	LAZARUS WHITE	73
	WALTER E. SPEAR	74
	ARTHUR S. TUTTLE	76
	LOUIS L. TRIBUS	76
	E. G. HAINES	77
	X. HENRY GOODNOUGH	78
	WILLIAM W. BRUSH	78
	THOMAS H. WIGGIN	79
	JOEL D. JUSTIN	83
	JAMES F. KEMP	85
	THADDEUS MERRIMAN	88
	CHARLES P. BERKEY AND JAMES F. SANBORN	89
1510	**SOME NOTES ON THE LOCATION AND CONSTRUCTION OF LOCKS AND MOVABLE DAMS ON THE OHIO RIVER, WITH PARTICULAR REFERENCE TO OHIO RIVER DAM NO. 18.**	
	By **William M. Hall**	92
	Discussion:	
	By THOMAS P. ROBERTS	132
	EARL I. BROWN	137
	WILLIAM W. HARTS	139
	L. M. ADAMS	142
	C. I. GRIMM	147
	B. F. THOMAS	151
	MALCOLM ELLIOTT	152
	FREDERICK B. DUIS	158
	W. H. MCALPINE	165
	GARDNER S. WILLIAMS	167
	MORRIS KNOWLES	168
	WILLIAM M. HALL	172
1511	**THE COMPARISON OF CONCRETE GROINED ARCHES AS AN AID IN THEIR DESIGN.**	
	By **Philip O. Macqueen**	180
	Discussion:	
	By THOMAS H. WIGGIN	190
	PHILIP O. MACQUEEN	196
1512	**TENTATIVE PLAN FOR THE CONSTRUCTION OF A 780-FOOT ROCK-FILL DAM ON THE COLORADO RIVER, AT LEES FERRY, ARIZONA.**	
	By **E. C. La Rue**	200

No.		PAGE
	Discussion:	
	By C. R. F. COUTLEE	218
	H. B. MUCKLESTON	219
	EDWIN H. WARNER	219
	F. A. NOETZLI	221
	KIRK BRYAN	228
	ARTHUR P. DAVIS	240
	J. C. STEVENS	245
	J. H. QUINTON	246
	ERNEST H. BALDWIN	249
	C. S. JARVIS	250
	SAMUEL FORTIER	252
	L. F. HARZA	256
	I. GUTMANN	258
	E. C. LA RUE	259
1513	**BOND STRENGTH OF WOOD PILES IN CONCRETE.**	
	By **R. R. Lundahl**	268
1514	**EXPERIMENTS WITH MODELS OF THE GILBOA DAM AND SPILLWAY.**	
	By **R. W. Gausmann and C. M. Madden**	280*
	Discussion:	
	By GEORGE G. HONNESS	306
	B. F. GROAT	307
	ROBERT FLETCHER	308
	I. GUTMANN	310
	ROBERT F. EWALD	312
	THADDEUS MERRIMAN	317
	R. W. GAUSMANN AND C. M. MADDEN	318
1515	**THE DESIGN OF STRUCTURAL SUPPORTS FOR TURBO-GENERATORS.**	
	By **Edward H. Cameron**	320
	Discussion:	
	By W. E. BELCHER	336
	AUSTIN H. REEVES	341
	F. A. ERICSON	342
	JAMES H. RICHARDSON	342
	F. M. BEER	343
	GEORGE A. ORROK	343
	R. VON FABRICE	344
	D. A. ALLEE	348
	EDWARD H. CAMERON	349
1516	**ANALYSIS OF COST OF FREIGHT SERVICE, GRAND TRUNK RAILWAY COMPANY OF CANADA.**	
	By **J. P. Newell**	351
	Discussion:	
	By J. G. SULLIVAN	385
	J. P. NEWELL	386
1517	**TECHNICAL PAPERS PRESENTED AT THE ANNUAL CONVENTION, PORTSMOUTH, N. H., JUNE 21, 1922**	389
	PROGRESS IN HIGHWAY RESEARCH.	
	By **W. K. Hatt**	390
	POLLUTION OF STREAMS BY PULP-MILL WASTES.	
	By **George C. Whipple**	393
	WASTES FROM PULP AND PAPER MILLS CHEMICALLY CONSIDERED.	
	By **H. W. Clark**	401

No.		PAGE
	THE TREATMENT AND DISPOSAL OF STRAWBOARD WASTES.	
	By H. B. Hommon	405
	RELATION OF WATER POWER TO THE PULP AND PAPER INDUSTRY IN CANADA.	
	By J. B. Challies and I. J. Johnston	411

ERRATA

Transactions, Vol. LXXXV

Page 255, Equation (22), for

$$\text{“ } M_0 = \frac{2\,p\,k^2}{6}\,\frac{1-\frac{x^2}{6}}{-\frac{x^2}{18}+4\,\frac{k^2}{L^2}\left(2-\frac{4}{3}\,x^2+\frac{5}{18}\,x^4-\frac{x^6}{54}\right)}\text{ ”, read}$$

$$\text{“ } M_0 = -\frac{p\,k^2}{3}\,\frac{\left(1-\frac{13}{60}\,x^2+\frac{5}{280}\,x^4-\ldots\right)}{\frac{2}{45}\,x^2+\ldots+8\,\frac{k^2}{L^2}\left(1-\frac{2}{3}\,x^2+\frac{2}{9}\,x^4+\ldots\right)}\text{ ”}$$

Page 255, Equation (23), for

$$\text{“ } M = \frac{2\,p\,k^2}{6}\,\frac{2-\frac{7}{12}\,x^2+\frac{x^4}{24}}{-\frac{x^2}{18}+4\,\frac{k^2}{L^2}\left(2-\frac{4}{3}\,x^2+\frac{5}{18}\,x^4-\frac{x^6}{54}\right)}\text{ ”, read}$$

$$\text{“ } M_1 = \frac{p\,k^2}{3}\,\frac{\left(2-\frac{8}{15}\,x^2+\frac{2}{35}\,x^4-\ldots.\right)}{\frac{2}{45}\,x^2+\ldots.+8\,\frac{k^2}{L^2}\left(1-\frac{2}{3}\,x^2+\frac{2}{9}\,x^4+\ldots.\right)}\text{ ”}$$

Page 469, line 25, for “It is essential that streams and lakes be protected against pollution, as in the future, all large public water supplies are, or must be, derived from surface sources”, read “It is essential that streams and lakes be protected against pollution as all large public water supplies are, or in the future must be, derived from surface sources”.

Page 1141, line 4 from bottom, strike out the words, “as to”.

Page 1142, line 17, insert the word “reliable” after the word “less”, making the sentence read “The tests quoted by Mr. Wegmann * * * vary so greatly that even the mean value is less reliable than the former tests.”

ENGINEERING GEOLOGY OF THE CATSKILL WATER SUPPLY*

By Charles P. Berkey,† Esq., and James F. Sanborn,‡ M. Am. Soc. C. E.

With Discussion by Messrs. Alfred D. Flinn, George G. Honness, Lazarus White, Walter E. Spear, Arthur S. Tuttle, Louis L. Tribus, E. G. Haines, X. Henry Goodnough, William W. Brush, Thomas H. Wiggin, Joel D. Justin, James F. Kemp, Thaddeus Merriman, and Charles P. Berkey and James F. Sanborn.

Synopsis

This paper deals with the geological features involved in the location, design, and construction of the Catskill Water Supply System of the City of New York.

The purpose is to discuss the intimate relation of applied geology and certain phases of engineering work, to present illustrations of the method used by the engineers in solving, through the correct use of geological information, some of the problems involved, and to show the relations of these engineering problems to the natural features and conditions of the country in which the work is located.

General Conditions

In planning the construction of a water-works system comprising an aqueduct more than 100 miles long, together with several dams and other structures, the choice of location, design of structures, and details of construction were greatly influenced by the form, relief, and underground condition of the

* Presented at the meeting of October 4, 1922.

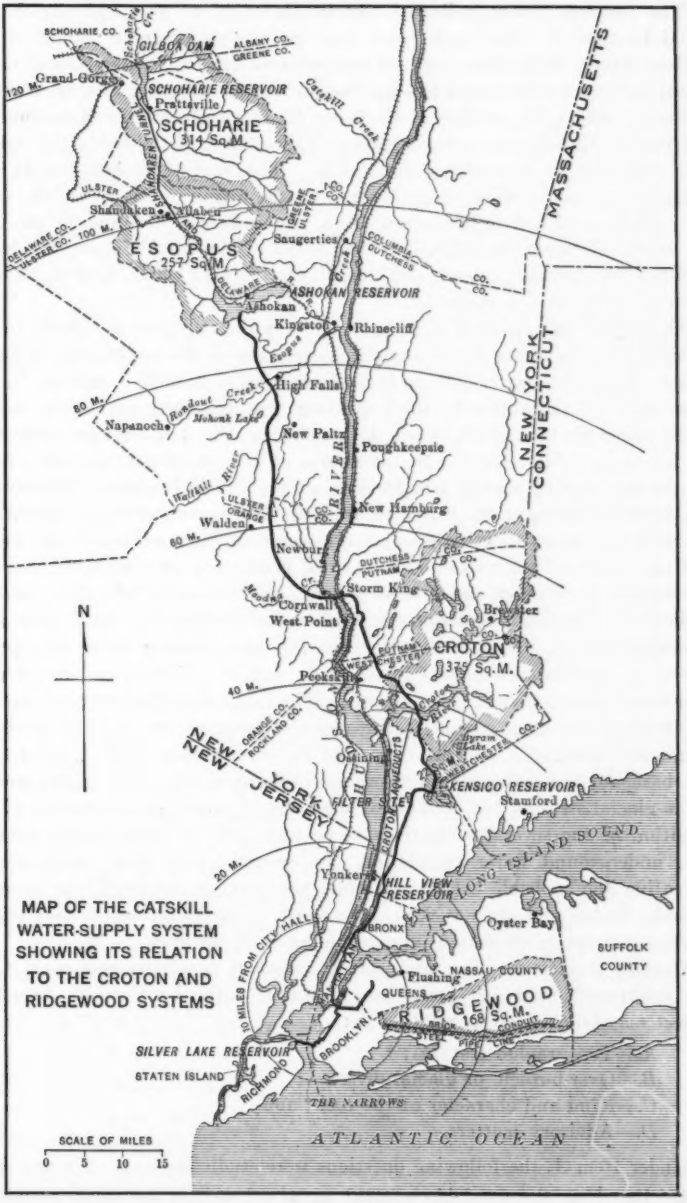
country traversed. Seldom in a large public enterprise of this kind, has so much trouble been taken to discover and to work out the important relations of topographic form and underground structure, and to apply the results of these studies to the problems of location, design, construction, and operation of the completed system. Indeed, it was necessary to success that all the conditions be known in detail. The selection of proper dam sites, with foundations sound enough to support the enormous weight of the dams and impervious enough to prevent leakage, demanded a careful investigation and study of all the intricacies of the physical condition and behavior of the ground. The expedient of conveying water in tunnels driven deep in bed-rock, under great hydrostatic pressure, was adopted only after sufficient information was available to give confidence in the general stability of local geological conditions.

The importance of these conditions in controlling the location of the aqueduct is well illustrated in the choice of the crossing of the Hudson River, the final selection of which involved a change in the position of the entire aqueduct line west of the river. Fig. 1 is a map of the Catskill Water Supply System. The principal types of construction included in the project are, as follows:



(*a*) Three high masonry dams;
(*b*) Several miles of earth dikes with core-walls; and
(*c*) An aqueduct, made up of the following parts:

Cut-and-cover aqueduct	51.0 miles
Grade tunnel (including Shandaken Tunnel)	31.7 "
Pressure tunnel	35.6 "
Pressure aqueduct	4.8 "
Steel pipe siphons	6.2 "
Pipe conduit	15.4 "
Total	144.7 miles

In the construction of pressure and grade tunnels, sixty-seven working shafts, from 150 to 1 100 ft. in depth, were sunk.

Geological Investigations

The development of the Catskill Water Supply System has been influenced by geological factors to a greater extent than is usual in most engineering enterprises. This is due in part to the great distance the water must be carried to reach New York City, the topographic and structural complexities and peculiarities of the intervening country, and the general plan of operation chosen for this particular system. Because of the type of design of the Catskill Aqueduct and the peculiar relief of the country, it was evident early in the work that many grade tunnels would be required to pierce the mountain ridges standing above hydraulic grade along any possible route. It was also found that it would be more economical, and would result in a more successful and permanent public work, if the valleys and river courses which lie much below hydraulic grade, were crossed by pressure tunnels constructed in the bed-rock.

MAP OF THE CATSKILL WATER-SUPPLY SYSTEM SHOWING ITS RELATION TO THE CROTON AND RIDGEWOOD SYSTEMS

FIG. 1.

The earliest studies indicated certain places where thorough exploration would be needed. One such place was the trough or inner valley of the Hudson River, which presented an unusual problem in the question of depth to bed-rock. To collect and to state the broad facts relating to this situation and many others, the services of Professor W. O. Crosby, of the Massachusetts Institute of Technology, and of Professor J. F. Kemp, of Columbia University, were obtained as Consulting Geologists. The studies undertaken by the geologists covered a wide range, bearing on the origin of the rocks, the processes which modified or preserved them, the influence of climatic changes, the effect of former elevation and depression of the earth's crust, the interpretation of surface features, and many other factors which tend to modify, preserve, or to destroy the rocks.

In projects of this kind it is important for the engineer to submit to the geologist certain rather definite questions relating to the engineering requirements. It is not practicable to investigate wholly unrelated matters in the early stages of the work. In the beginning, the geologist's advice was sought in directing the exploratory work, to supplement the data already secured as the boring work developed. In the course of the investigations and studies for the engineering design and location of the Catskill System, information was secured relating to the suitability of materials of construction, comparison was made of factors affecting the cost of excavation, facts relating to the water-bearing quality of the rocks and soils to be penetrated were obtained, and the influence of the rock on the structures contemplated was noted. One question studied was whether the tunnels far below the surface may be damaged by earthquake shock, or are otherwise unstable, and whether there are special sources of trouble or weakness in the rock, such as acid-bearing waters with their own peculiar destructive influence. The range of information ultimately required covered such special features as a comprehensive regional study of pre-glacial topography and drainage, and the distribution of the glacial drift as a basis for indicating the location and probable depth of the buried gorges of pre-glacial streams, the contour of the bed-rock surface, a discussion of the condition of the several formations to be met, their behavior under excavation, underground water circulation, the occurrence of zones of weakness indicating the probable extent of tunnel roof support required, the location of folds, faults, and other rock features, with a consideration of their effects on the construction operations and permanence of the work.

General Questions.—The engineering questions involving geological facts and interpretation which arose in connection with the Catskill Aqueduct project may be grouped as relating to:

A.—Topographic features;
B.—Over-burden, or glacial drift;
C.—Kind and character of the rock; and
D.—Advisory matters.

Under Item *A*, the following questions were studied:

1.—Based on the available contour maps, where are the most promising sites for the particular structures under consideration, for example, the main dams for storage reservoirs?

2.—Do the surface features indicate whether the relief is controlled by the glacial drift or by erosion of bed-rock?

3.—Considering the larger topographic features, such as the main valleys and their origin, is there any likelihood of finding deep buried gorges requiring extensive exploration?

Under Item *B*, the following questions arise:

1.—What is the thickness and distribution of the over-burden, or drift, in the area involved?

2.—Is there unusually deep cover at any particular place, or a pre-glacial gorge of uncertain depth?

3.—What is the character of the over-burden? Is it residuary soil, stream deposit, or glacial drift? Is it impervious or very porous? Will it be firm or cave in excavation? Are extensive exploratory borings or test-pits required?

Under Item *C*, some of the questions are:

1.—What is the probable rock-floor contour or profile? What is the rock formation or kind of rock forming the floor, its quality, and structural character? Is it porous or reasonably impervious?

2.—Is there danger of weathering, disintegrating, or swelling of the rock in tunnel excavation or open cuts? Is there likely to be considerable depth of decayed or weathered rock on top of the ledge proper?

3.—Is the rock massive or bedded? If sedimentary, what is the structural attitude? Is it faulted and folded? If the rock formation at a particular location or depth is questionable, is there a possibility of finding more satisfactory conditions either by a shift of line to a new location, or a change in depth?

Under Item *D*, the following questions may arise:

1.—Where should the exploratory work be located and the borings placed, and to what depth?

2.—Is the proposed project feasible from a geological standpoint, or are the natural difficulties insurmountable?

3.—Are there any special precautions to be taken at certain points during construction? What special points must be covered in the contracts?

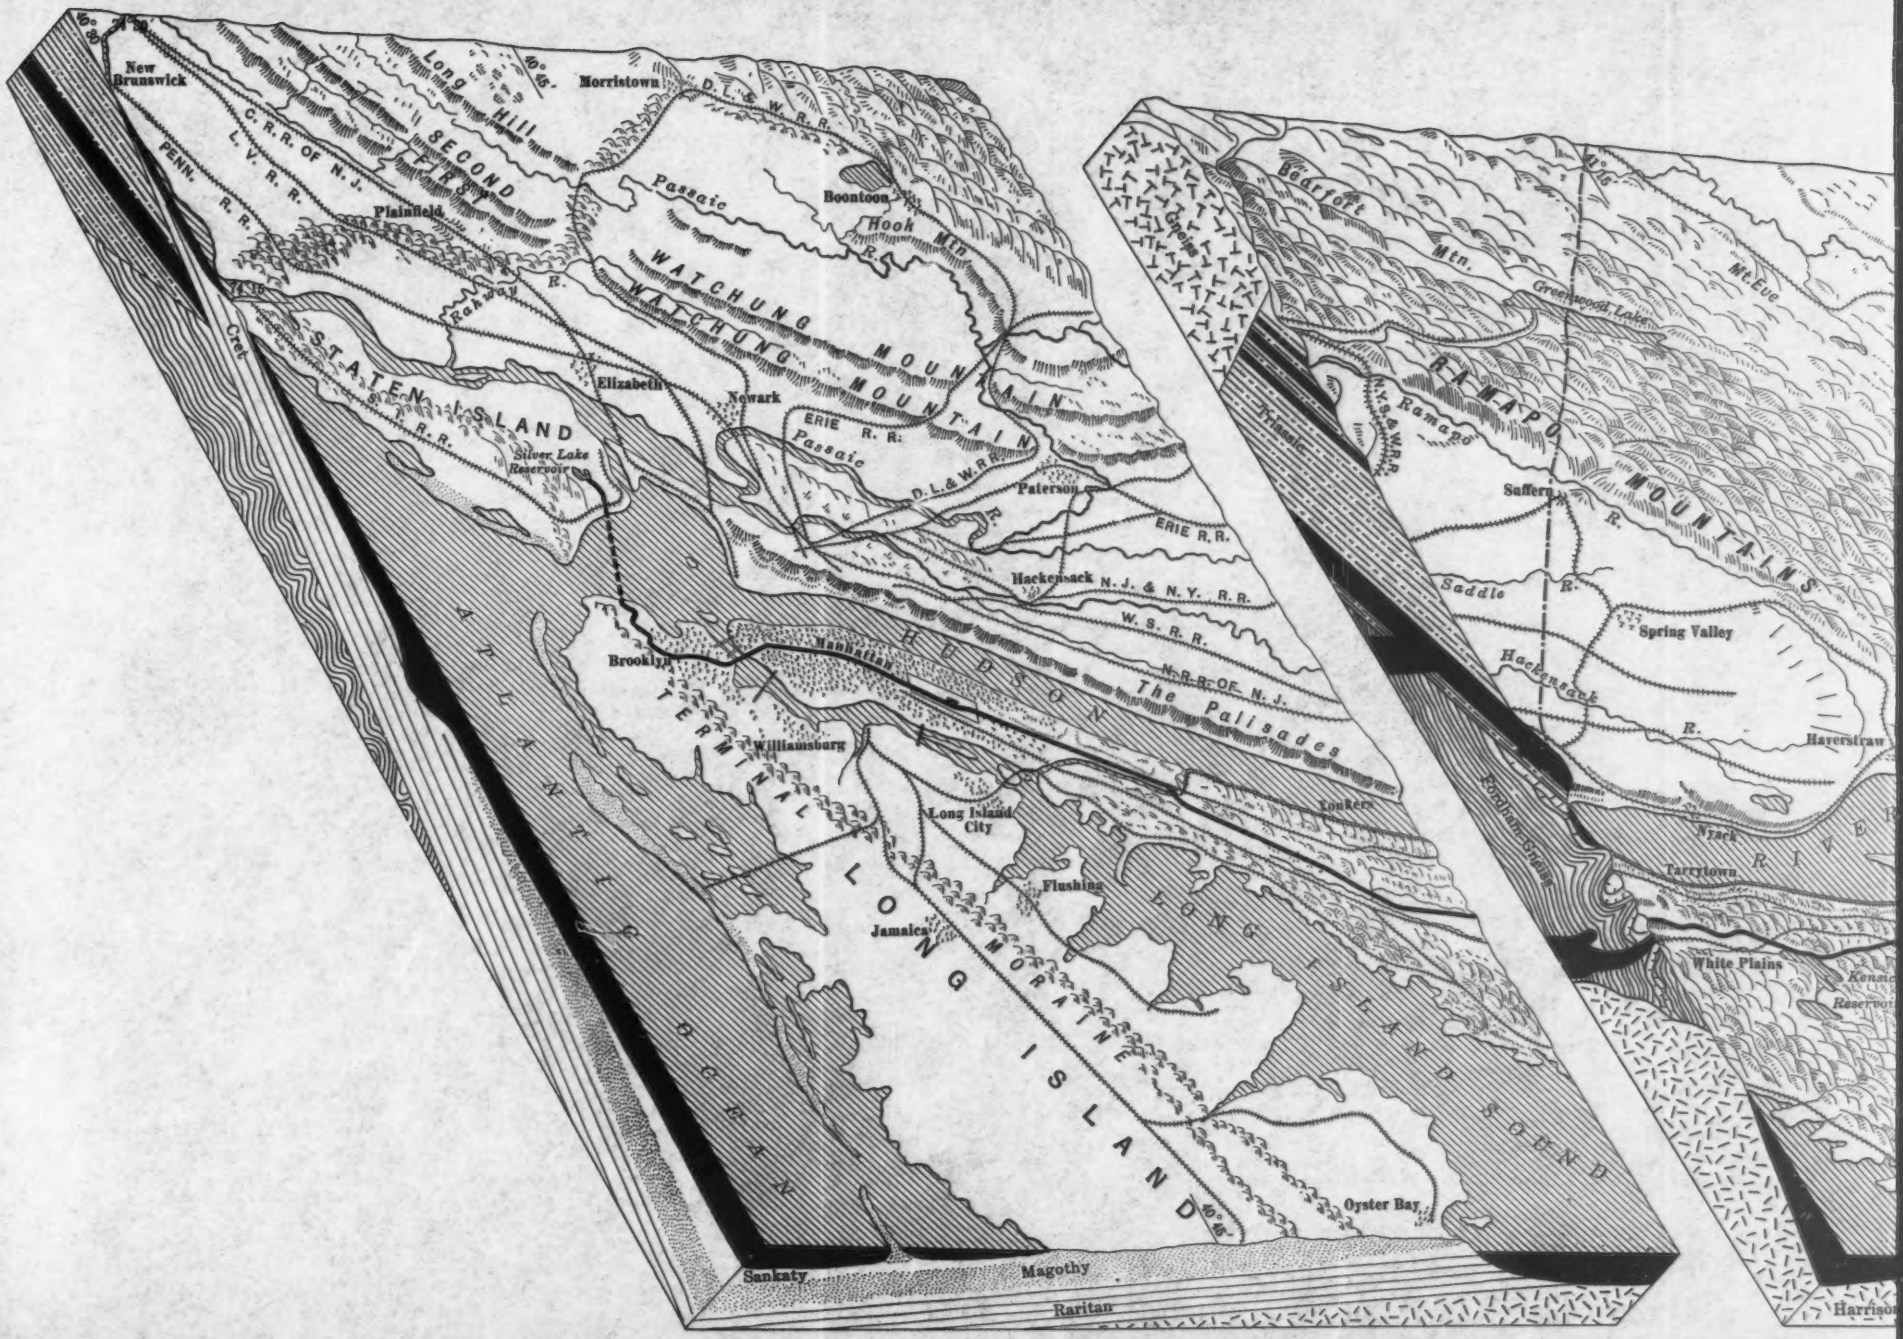
4.—Is the locality capable of producing suitable stone for use in construction?

5.—Is there any likelihood of the disturbance of local conditions by the work of construction, such, for example, as change of water level, interference with local water supply, or weakening of foundations? Are the geological conditions such as to expect claims for either temporary or permanent damages due to construction?

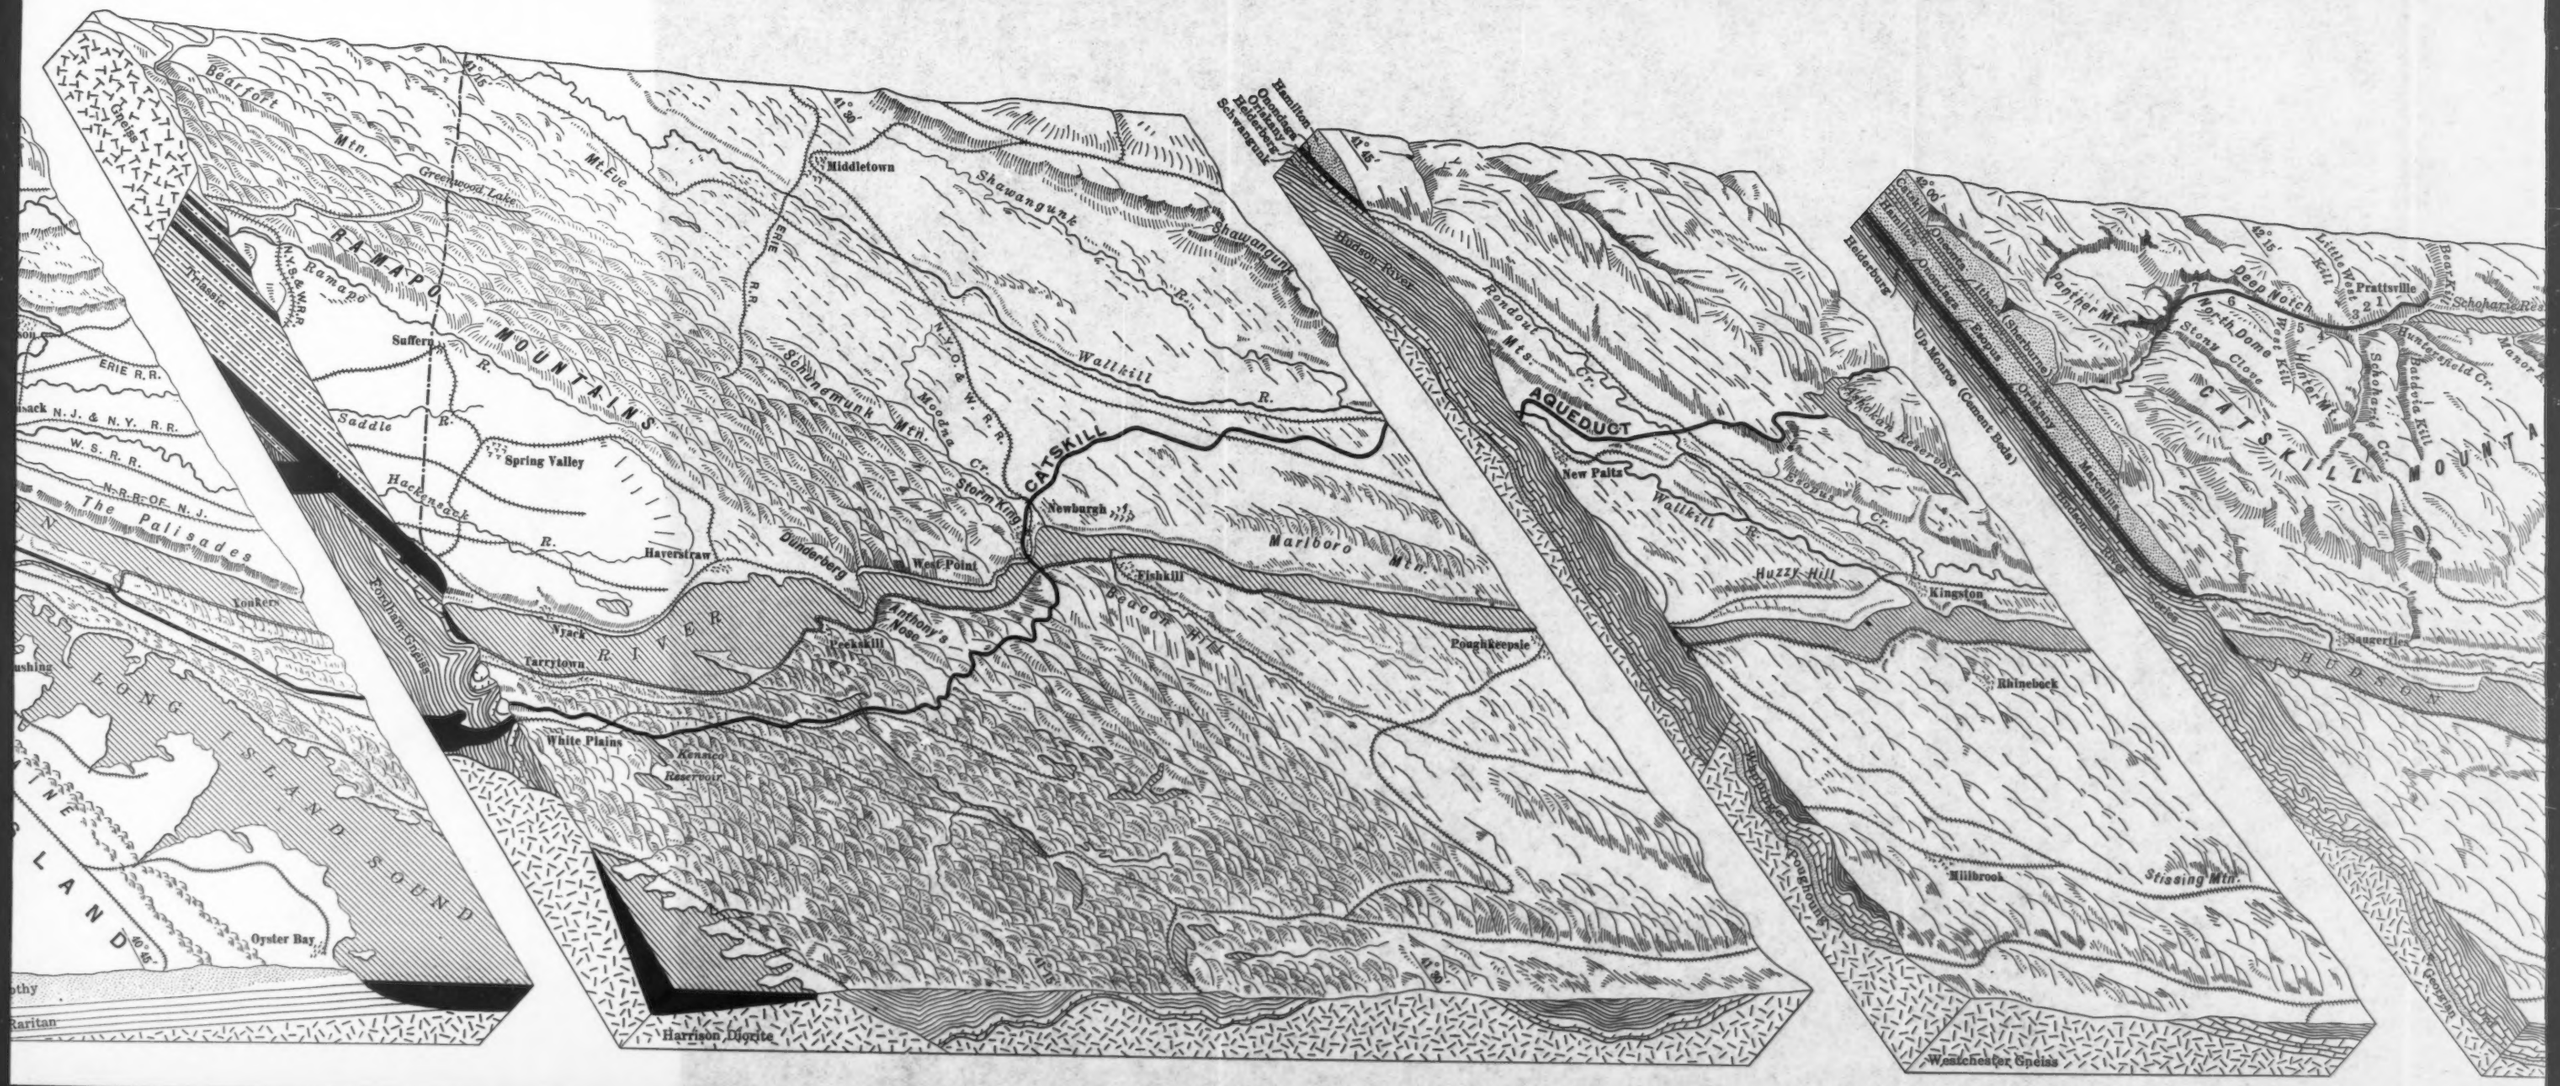
The most economical method of exploration as far as it can be stated in general terms is to base it first on a thorough geological study, to check and interpret all data as gathered, and modify, if necessary, any additional exploratory work in accordance with the results already secured. A working hypothesis is essential. The engineers found it helpful to obtain the advice of a geologist in the interpretation of the exploratory borings as these were

made, so that the next hole could be located at the spot most likely to give further results in the light of the existing knowledge. By this method, much time was saved and the borings were made to give useful information. The methods of securing underground data included, in addition to surveys and mapping, the use of (1) test-pits, shafts, and trenches; (2) tunneling; (3) borings of various kinds; (4) pumping and pressure tests of drill holes; (5) laboratory tests, and microscopic examination; and (6) chemical analysis.

Geology of the Region Traversed by the Catskill Aqueduct



The relief features and geologic structure of the country traversed by the Catskill Aqueduct is more complex than is generally the case in such a limited area. This region has been affected by mountain foldings and accompanying dynamic disturbances at least three times. The area extends from the undisturbed interior plateau type of country (as represented by the Catskill Mountains), across the entire belt of Appalachian folds (as represented in the Middle Hudson Valley of New York), and the still earlier Taconic deformation belt (as represented in the older sedimentary rocks, especially the Hudson River slates north of the Highlands), the mountainous belt of very ancient geological formations (as represented by the Highlands with the Piedmont belt of crystalline rocks), to the Coastal Plain, including the newer formations along the present seashore. It is a complex region of a long and involved history. Fig. 2 shows the geologic column, representing the succession and variety of rocks encountered in the Catskill Water Supply development. Plate I shows a block diagram of the physiographic features, together with the underground geologic structure of the Lower Hudson region and the course of the Catskill Aqueduct.



Beginning with the areas occupied by the water-sheds, the chief types of country are, as follows:

The Catskill Plateau, characterized by an elevated upland of little disturbed, rather flat-lying sediments, dipping gently westward, made up mostly of fine-grained sandstones and still finer shales.

South of the Catskill area is the Appalachian Province forming a belt running northeast-southwest, paralleling the eastern edge of the Continent. This belt has shared in the folding and other movements which have been responsible for the structural complexity of the strata and have controlled the relief habit of the present surface. A part of this belt, now somewhat lower and apparently less ridged than the remainder, forms what is known as the Great Valley. The compressive or mountain-building forces which produced the Appalachian belt, acted in a general northwesterly direction and produced folds of remarkable continuity, accompanied by a series of great faults running parallel with the main ridges and valleys, or generally northeast and southwest. The whole province is crossed by the Catskill Aqueduct.

Still farther south the country changes again, and one finds there the ancient Archean land mass, represented to-day by the gneisses and granites of the Highlands. In this belt, all the rocks are crystalline. They belong to an extremely old series, possibly the oldest known in the eastern part of the United States. Doubtless, originally many of them were sediments similar to those

occupying the districts farther north, already described; but, subsequently, they were affected by metamorphism and invaded by igneous intrusions of many kinds, especially by granites, and thus became not only much modified from their original condition, but also much disturbed and distorted. In their present condition, they form the most complex belt with which this work has had to deal.

Although the Highlands proper is a narrow belt not more than 20 miles wide, the same kinds of rocks to a large degree extend continuously on the east side of the Hudson River to New York City. For 50 miles, the aqueduct has been located through and over these complex rocks. The southerly part of this unit has more moderate relief than the Highlands proper, and its surface gradually becomes lower and lower, passing beneath sea level in the vicinity of Long Island Sound and New York Bay, only the Highlands Belt being mountainous.

The last of the distinctly different districts follows the immediate border of the Atlantic between Long Island Sound and the sea, including also a part of Staten Island. It is the northerly extension of the great coastal belt which, farther southward, becomes much wider and much more prominent as a physical unit. This belt is characterized by simple sedimentary strata of clay, sand, and gravel which lie almost flat, but really dip gently toward and beneath the sea. They are the simplest of the formations with which this work has been concerned, but are of prime importance, especially in connection with the water sources of Long Island. These great provinces differ strikingly in physical make-up, structure, and age. Each is complex, is structurally a group of physical units or formations distinguishable among themselves, and each presents its own peculiarities of behavior and geological significance.

Geological History.—The oldest of all the rocks are certain parts of the crystallines of the Highlands. These rocks are doubtless old sediments formed in the sea and by running water. They were a great series which was folded into mountain ranges in ancient times. Subsequently, they were invaded by immense floods of igneous material, which literally swallowed large parts of the solid foundations of that time and formed huge igneous masses now appearing as granites and other massive rocks. Rocks of intermediate composition were formed, doubtless by a mixture of the two original types—the sediments and the invading igneous material. This is well shown on the geologic profile, Plate II, from the Catskill Mountains to New York City along the aqueduct line.

These changes took place at great depth. The superficial formations of that time have been carried away by erosion. Only the roots of this ancient mountain range are now exposed, and they are the crystalline rocks of the Highlands. How much erosion took place no one can say, but after ages of erosion, so long indeed that the rivers of that time and the sea had cut away all the superficial material and had exposed the already cooled and crystallized igneous masses, the sediments that now form the other rocks began to accumulate. The land area lay along the Atlantic border and extended an undetermined distance into the present Atlantic Ocean. The sea lay to the west and in it were deposited the sediments carried down from this

land area, first the sandstone, limestone, and shale of the present Hudson Valley, and after several thousand feet of these sediments had accumulated a new mountain folding and another period of erosion took place.

When deposition began again, it formed the great series of sediments that now lie above the Hudson River shale series. The Shawangunk conglomerate was the first, and on it were accumulated, one after another, the shales, limestones, and sandstones that now constitute the rocks of the Rondout Valley and the Catskill Mountains. Then came the Appalachian Mountain-making period, the last great folding movement to affect this region. Since that time, conditions have been completely reversed. The region to the west became a continental area and the re-adjusted drainage from this new continental area carried the sediments of subsequent time toward the east into the Atlantic. A long period of erosion followed, and, with the shifting of levels, the Atlantic gradually encroached from the east, covering a part of the old land area that originally furnished most of the earlier sediments.

In this long period of erosion and unchanged sea level, there was opportunity for the streams of the new Continent to wear the whole region down almost to a plain. The development in this "almost-plain" took place in the Cretaceous period, and, therefore, is referred to as the "Cretaceous peneplain." During part of this time and, subsequently, sediments have been accumulating on the Atlantic Coast. These are simple beds that are not much distorted. The Cretaceous peneplain still persists in a somewhat fragmentary form, because of much subsequent erosion. From a high elevation it can be plainly seen in distant landscape, as, for example, in the level sky-line of the Hudson Highlands, the Shawangunks, and parts of the Catskills, and more definitely in the remarkably uniform seaward slope of the crystalline rocks south of the Highlands passing under Long Island out beneath the sea. Its existence is shown by the boring profiles across Long Island to depths of 1 000 ft. and more below sea level, where the soft Cretaceous beds of the Coastal Plain lie on the old erosion floor of that time.

An elevation of the Continent of from 1 000 to 2 000 ft., during the Tertiary period, gave the streams a steeper slope toward the sea, with greatly increased velocity and cutting power, so that the old Cretaceous surface was deeply dissected by the streams cutting new valleys along the more easily eroded rocks. In the course of time, a new base level of erosion was reached in places where the rocks were comparatively soft, such as limestones and slates. This new peneplain, however, was never finished. The region was elevated again before the erosion was completed, and new trenches began to be cut by the streams. Traces of this Tertiary peneplain are readily seen, however, in the rather even stretches of ground, at 300 to 500 ft. above sea level, in the broad valleys of the Hudson and its tributaries. The importance of the questions previously discussed relates closely to the problems in the location of the Catskill Aqueduct, in the depths of old buried stream valleys and their effect on the location of tunnels. The Tertiary peneplain was a feature of great significance in determining the course and hydraulic grade of the aqueduct. The 15-mile section of cut-and-cover aqueduct from the Wallkill to the Hudson River is made possible at its present grade by the

existence of this old peneplain. The subsequent continental elevation that ended the development of the Tertiary peneplain and caused the renewal of trenching, finally started the glacial epoch, and an entirely new set of conditions were thus established, which led to changes of far-reaching importance. This elevation probably ultimately amounting to several thousand feet, at first simply increased the cutting power of the streams and resulted in renewed trenching of the valleys, with the development of rather narrow deep gorges, extending far below the general Tertiary base level. These gorges still remain beneath the glacial drift cover, some of them extending several hundred feet below sea level.

The Glacial Period.—The ice invasion that followed, covered the entire region, including the Catskills and the Highlands, the ice occupying even the highest summits and spreading southward to Long Island. There, the ice melted, forming the Terminal Moraine which extends the length of the Island and crosses the Narrows to Staten Island, thus marking the southern limit of the great continental ice sheet. At the height of its activity, as it moved southward, the planing action of the ice mass smoothed the tops of hills and ridges, ploughed deeper in some of the softer material of the valleys, and scraped hard against all exposed northerly slopes. At the same time, particularly as the ice finally thawed, the deeper canyons and valleys were buried with glacial drift, thus modifying greatly the surface contour of the country and tending by these processes of erosion and deposition, to smooth the more rugged earlier topography. One of the results of this action is the buried channels and drift-filled gorges. The present streams scarcely anywhere flow in their original channels, nor even on the old valley bottoms. On this account it was necessary repeatedly to determine, by boring, the location and the depth of these old pre-glacial channels.

The damming of valleys by glacial ice and drift created lakes and gave opportunity for the development of silt deposits in them. Subsequent partial or complete removal of such barriers and final drainage of these temporary reservoirs are factors of important bearing in this region. The Ashokan Reservoir occupies, in part, one of these glacial lake basins. The material left behind by the ice sheet is a mixture of mineral and rock matter derived from the removal, transportation, and deposition of former residuary soils and partly disintegrated rock gathered up as the glacier moved slowly over the surface of the country. Some of it is a mixture of pebbles, boulders, sand, and clay, which was not assorted by the action of water. This is the so-called "glacial till", also known as "hardpan", when consolidated. Other parts of the drift were worked over by the water from the thawing ice and thus were more or less assorted so that the materials became separated as deposits of sand, gravel, and silt or clay. These deposits constitute the so-called "modified drift" deposits, which, unlike the till, are generally loose and unconsolidated.

It would be a comparatively simple matter to classify these glacial materials and judge their behavior if they were as distinct, continuous, and uniform from top to bottom as the average rock stratum. However, they are much more likely to be variable in every respect and the different types of these

materials grade one into another in a most confusing manner. They exhibit important differences in their capacity for holding water. Thus, the character of the drift becomes an important factor in the choice of location for dams and dikes. In fact, they were controlling factors in the location of the Ashokan Dam.

Ancient Drainage.—In a study of the possible crossings of the Catskill Aqueduct under the Hudson and its tributary streams, the old courses of the pre-glacial channels and particularly their depths, were vital factors in the design and location of the pressure tunnels.

In this district there is only one main drainage channel, the Hudson River, to which all the other streams are tributary. These tributaries have attained their present courses by the general northeast-southwest strike of the rock formations, the different members of which are strongly contrasted in their resistance to erosion. It thus happens that whereas all the tributaries on the east side of the Hudson are direct, those on the west side are retrograde, that is, flow somewhat opposite to the direction of flow of the master stream and join it at an obtuse angle. The Wallkill River is a remarkable example of this. It rises within 40 miles of New York Bay, and flows northeasterly, following the formational direction for 75 miles, getting farther and farther away and finally reaching the Hudson nearly 90 miles from the sea. On account of the glacial drift cover, many of these stream valleys are heavily filled and the present stream courses diverge greatly from these former lines. Still, the old courses were of greatest importance in the problems of the aqueduct. Thus, it happens that a working knowledge of the origin and habit of the pre-glacial drainage has been of greater practical service than the simple statement of its features would lead one to expect.

The Catskill Mountain Water-Sheds

The selection of the Catskill Mountains as a source of the new water supply of New York City was made because this area was found to be the one which, by reason of its large, sparsely inhabited, and well-wooded mountain slopes, is certain to yield an adequate quantity of water of exceptional softness and purity. The site chosen for the main storage reservoir, 100 miles from New York City, in the southern edge of the Catskill Mountain area, is at such an elevation that the water from it can flow by gravity through the aqueduct and distribution systems, thus eliminating the cost of pumping. Because of the steep mountain slopes, the water runs rapidly down the rocky stream beds, encountering on its way almost no swampy ground or stagnant ponds. Even almost all the water that sinks into the soil and enters bedrock returns clear and pure to the regular drainage courses at the lower levels in the immediate district, because the beds lie nearly flat and have many interbedded tight shale members to obstruct the downward course of the water.

The gathering ground in the Catskills lies entirely in a region of sandstones and shales, without much admixture of limy fossil remains and no limestone beds. Such rocks are very resistant to solution and, for this reason, the water which flows over and percolates through them, dissolves so little mineral salts that a water unusually soft and pure is supplied.

The sedimentary beds consist of alternate layers of hard sandstone and soft shale, with wide variations in the quality and thickness of individual beds. In many places, the sandstone is of the quality known as bluestone, and has been extensively quarried. Generally, the strata dip to the west at a small angle, and there is no marked deformation. In a broader view, the region may be regarded as a deeply dissected plateau of which the rocks of different hardness, lying in beds dipping gently westward, give form to the back slope of the uplands, whereas the edge of the Catskills toward the Hudson Valley presents a pronounced eastward-facing scarp, rising abruptly several hundred feet above the valley floor. Erosion has been carried so far that the most elevated remnants have a mountainous aspect. Below these high peaks, the country is more open and uniform, being part of an old base level, or peneplain, judged to be the Cretaceous peneplain referred to previously. Deep canyons and high cliffs are common, with piles of broken rock at their bases. Glaciation has modified the original rugged features, especially the minor details to some extent, and glacial deposits have changed the drainage in many of the valleys, so that the present streams do not follow the courses of the old pre-glacial channels.

The dark sandstones, locally known as bluestone, with the associated shales, are simple sedimentary formations of great lateral extent and thickness. They were laid down as delta deposits, the sedimentary material varying from coarse sand and even small pebbles to the finest silt. The shifting of depositing currents and changes in the supply of materials resulted in a complex structural relation of the beds with frequent variations in the grade of the rock.

This variability in the quality of the rock within short distances is a striking feature in this formation, and was important in the selection of quarries for construction materials. The variation in the grade of the rock also has an important bearing on questions of value, as was illustrated in several large claims for damages where lands were condemned and taken by the City for the Ashokan site. The bluestone, shown in Fig. 3, is a rather fine-grained, dense, and impervious sandstone, very resistant to weathering. Blocks of the bluestone were used in the Cyclopean masonry of the Olive Bridge Dam, and the Gilboa Dam and Spillway will be faced with this material, which is as durable as the best granite. Bluestone is commonly used in New York City for curbs and sidewalk flags.

The Ashokan Reservoir

The main storage reservoir of the Catskill System has an available capacity of 128 000 000 000 gal. The principal structures which form this reservoir are the Olive Bridge Dam, built of masonry, across Esopus Creek, the earth dikes which close the gaps between the hills forming the sides of the reservoir, the dividing dike and weir, which separates the reservoir into two basins, and the waste weir.

The west basin of the Ashokan Reservoir in the Catskills, is shown in Fig. 4. The level top of the old plateau, deeply dissected by streams, is well shown; the stratified rocks dip to the west (left) at a low angle. The flow-line elevation of the reservoir is 600 ft. above tide and the maximum elevations

FIG. 3.—SANDSTONE USED ON CATSKILL WATER SUPPLY SYSTEM.

FIG. 4.—VIEW OF WEST BASIN OF ASHOKAN RESERVOIR.

of the mountains in this view are about 3 500 ft. Slide Mountain is 4 200 ft. in elevation.

Its geologic setting is as follows: The continental ice sheet, following the trend of the Appalachian Valley, moved in a southwesterly direction, as shown by glacial scratches. Local glaciers originating in the Catskills may have moved down through some of the main valleys such as the Esopus, but their effects are not very pronounced, and the general ice movement was transverse to this part of the valley. The character of the glacial deposits shows that the ice must have stood in the vicinity of Olive Bridge for a long time in the closing stages, forming an extensive dam, while the melting ice produced a glacial lake in the valley up stream from this dam, where silt and mud were deposited in the form of stratified sand and clay.

Heavy till deposits still form an effective dam at Olive Bridge, but the waters of the lake escaped along the western edge of the valley and cut through the drift, finally reaching bed-rock and cutting a new gorge in it. At the same time, the stream farther up the valley carried off great quantities of the soft and easily removed lake deposits originally laid down in the glacial lake, thereby further emphasizing the basin-like form of the reservoir site.

Geologic Conditions Affecting Dams.—The influence of geologic factors in the selection of dam sites is always considerable. A dam project is seldom too thoroughly studied or a site too carefully explored. Frequently, it is taken for granted that conditions are acceptable, which subsequent development prove to be dangerous. Expensive explorations, also, may be made, which intelligent judgment would show were unnecessary.

Studies of the dam sites of the Catskill project included investigation of the following subjects:

1.—Enough of the geology of the region to be certain that no important geologic influences were overlooked.

2.—Detailed topography over the site and adjacent areas.

3.—Bed-rock contour.

4.—Character of material overlying the rock floor, particularly in regard to porosity and behavior under construction disturbance.

5.—Character of bed-rock. Kind and quality of rock. Condition of the rock with respect to solution or decay or disintegration. Structural features, such as joints, bedding planes, faults, or crush zones. Porosity of the rock and nature of the water circulation, whether through the body of the rock or only along the bedding planes or joints.

6.—Exploration of underground conditions by borings or other means, with directions as to their location and order. Interpretation of boring data with tests of the ground through the borings themselves.

7.—Related questions. Local sources of material for construction, and comparison as to quality and cost, with other available materials. Need of treatment of foundation by grouting or otherwise. Probability of earth movements of such magnitude as to injure the structures. Possibility of claims for damages.

In the selection of a site for the Ashokan Reservoir several locations were investigated. The number of practicable sites was finally reduced to two, the "Olive Bridge" and the "Tongore" sites.

The Olive Bridge Site.—The nature of the drift in the trenches, shafts, and surface exposures of the vicinity indicated that the drift at the Olive Bridge site had been, at one stage in the glacial history of the locality, a natural dam and that water had been successfully held above it to an elevation of 530 ft., and perhaps more. The lowest materials in contact with the bed-rock are heavy stony till, laminated till, and stony laminated clays, all good impervious material making tight contact with the rock, and although a deep pre-glacial gorge lies underneath, at one side of the valley, it is filled with this tight drift, and there is no question whatever about its water-tightness.

Sands and laminated clays are extensively developed immediately up stream from the site. These looser materials grade into the heavy till material of the site proper and approach so close that occasional pervious streaks extend well into the westerly edge of the site. They do not at any point extend continuously through this ground, however, and, consequently, the present barrier, as it stands, is practically impervious. On account of the poorer quality of the drift up stream, the dam site was located as far down stream as engineering considerations permitted.

The Tongore Alternative Site.—At the Tongore site, the bed-rock floor in the buried gorge is at least 100 ft. deeper than at Olive Bridge. In the deeper parts, below the 400-ft. elevation, the deposits as indicated by the wash borings, are interpreted as a fairly continuous succession of stony drift, stratified sands and gravels, and laminated sands and clays belonging to two or three different early stages of accumulation. On this material, the heavy upper till was laid down. These overlying deposits are, as a whole, essentially impervious, but the lower 150 ft. will allow ready movement of water, especially laterally. This seems to be indicated also by the rather persistent occurrence of springs and soft wet places along the creek bank at about this level, both above and below the site.

Because of the higher bed-rock at the Olive Bridge site, the more uniform and impervious quality of drift deposits, the more massive cross-section of the barrier of drift on the north side of the site, and the glacial geology connected with the development of these features, that site was considered the preferable location for the dam on Esopus Creek. After the site was selected, the rock beneath the proposed dam was explored in detail by numerous core borings, and the holes were tested for the purpose of locating the position and permeability of seams in the rock. The bearing power and permanence of the blue-stones and shales beneath the heavy masonry structure and the possibility of creep of the softer shale members were also investigated.

The Schoharie Development

To complete the Catskill Water Supply System, the Schoharie water-shed is being developed by the construction of the Gilboa Dam which will form the Schoharie Reservoir. From this reservoir, the water is to be diverted

through the Shandaken Tunnel, now under construction, and will flow down the channel of Esopus Creek into the Ashokan Reservoir. Schoharie Creek lies on the north side of the divide from Esopus Creek, in the higher region of the Catskill Mountains. The Esopus flows out of the Catskills through the southerly gateway toward Kingston, N. Y., and the Hudson River, and the Schoharie flows north to the Mohawk River, near Amsterdam, N. Y. The water-shed, 314 sq. miles in area, is similar in character to that of the Esopus, chiefly steep mountain slopes covered with forest growth. The underlying rock consists of sandstones and shales through which the 18-mile Shandaken Tunnel is driven.

Several sites were investigated for the location of a dam on Schoharie Creek. The controlling geological features in the selection of such a site were the relation of a deeply buried inner gorge cut down into bed-rock by the interglacial stream and the quality and structure of the glacial drift deposits above the rock.

The Devasego Falls Alternative Site.—Of all the sites examined, that at Devasego Falls at first appeared to be the most promising from the standpoint of economy, on account of the favorable topography. At this location, a ridge of glacial drift extends into the main valley from the west and seems to have formed part of a dam across Schoharie Creek in late glacial time, causing a lake to form on the up-stream side to the south. The modern stream has trenched through this drift ridge, but at this point it is lodged far to the east side of the valley, where it soon cut into the rock of the valley side and is still cutting in this narrow post-glacial gorge with its inevitable water fall. This is known as Devasego Falls.

As the stream cut deeper and deeper through the drift obstruction, it drained the lake and has since carried out most of the loose fine sediment which formerly partly filled the basin. This easy erosion, together with the usual tendency to meander where the stream was free, has widened the valley above Devasego considerably, whereas the stream at the proposed dam site had become lodged in a rock cut at one side and the valley bottom was left still heavily obstructed with drift. It was proposed at first to take advantage of this natural barrier of glacial drift, which crosses and almost closes the valley, and to form a reservoir by building a short dam to close the gap made by the modern stream. As the depth of water in the reservoir thus formed would have been nearly 100 ft., the main question was to determine the degree of porosity of the material in the rather narrow drift ridge which would have to retain the water. The ridge is essentially a "kame deposit", formed at the edge of the ice during a melting stage. The material is, in part, transported and assorted and must have been laid down by water flowing from the mass of melting ice, and, in part, it is residual till probably frozen originally in blocks of ice, left to thaw in their present position. The whole is capped by impervious clay, a remnant of the later lake deposit. Formerly, the clay was undoubtedly much more extensive, constituting the topmost beds formed in the standing waters, but the stream has carried it nearly all away, except on top of this protected ridge.

It was anticipated that the mixed materials deposited by both water and ice would be in part porous and in part impervious. This condition was found on examination of the dry samples taken at frequent intervals in the borings. Furthermore, the sandy, porous material and the dense, impervious parts of the ridge were found to lie in no regular relation to each other. At first, it was hoped that these materials of different qualities might be so interlocked and so limited in lateral extent that no strata of porous material would extend continuously through the ridge. It was observed, however, during the drilling operations that the behavior of the ground-water was unusual. The water-table was very low and did not maintain even the general elevation of Schoharie Creek on the up-stream side of the ridge. There was also a tendency to lose water below the water-table as freely as above it. As the imperviousness of the ground was a vital factor, it was decided to investigate further the porosity of the material and the underground circulation by pumping tests. For this purpose, the casings were left in many of the holes. Water was pumped into one hole continuously for a period and the rise in the water was noted in the other holes. Prior to testing, all the casings were lifted from the rock floor to the first pervious layer, as indicated by the original records of each hole, and as the casing was raised the space was plugged with clay. This prevented the water from escaping down to and into the rock which was badly fissured. Water was then pumped into a centrally located hole, and the position of the water-table in the other holes was ascertained by soundings.

The geological sections previously developed by the borings had indicated certain pervious zones, and the results from the pumping tests confirmed the existence of these zones and, in addition, made it possible to trace them more or less successfully either to their limits or, at least, to establish their continuity. In general, a broad and extensive pervious zone, 1 000 ft. wide, 1 200 ft. long, and 30 ft. thick, the top of which is about Elevation 1 100, was found to extend in a northwesterly direction, reaching through the ridge to the under strata of the Bearkill. As a result of this investigation, and for the additional reason that investigations at the alternative site at Gilboa have shown decidedly better conditions there, the Devasego site was definitely abandoned.

The Gilboa Dam.—After investigating several favorable locations on Schoharie Creek, it was decided to locate the dam at Gilboa, N. Y., and create a storage reservoir in the valley of that stream. A line of borings across the valley showed that the bed-rock on the east side of the river is thinly covered with glacial drift and slopes gently to the west, and that the west side of the valley is filled with compact glacial till which fills the pre-glacial bed-rock gorge with impervious material. Although here, also, there is a much deeper old rock gorge beneath the drift of the west side of the valley, the natural obstruction now filling it, represented by the clay and till, is so effective a barrier that advantage can be taken of it in constructing the dam.

At Gilboa (Fig. 5), as at Olive Bridge on Esopus Creek, the present stream flows in a new rock channel in the side of the valley, made since the ice of the glacial period withdrew, and the old channel is buried under a

GEOLOGIC SECTION ON CENTER LINE OF PROPOSED DAM

Fig. 5.

great load of compact material. This is the ideal location for a dam in glaciated regions, but it is seldom that better conditions, even of this kind, are found than those presented at Gilboa. To meet the conditions, the dam at Gilboa will consist of a masonry section of Cyclopean concrete founded on rock in the present stream and the east end, and will join the till barrier of the west bank by means of a substantial earth dam with a core-wall deeply seated in the compact earth. As the form of the valley is a deep and narrow trench, the masonry section of the dam will be constructed as an over-fall spillway. The down-stream face will be made in large steps faced with natural stone. The face of the Ashokan Dam is formed of concrete blocks. The durable bluestone bed-rock of the gently sloping east bank will be stripped to form the over-flow channel, and the water will thus flow down the dip slope of the beds, parallel with the face of the dam, discharging into the gorge.

At the several quarries investigated, there are beds, 2 to 3 ft. thick, suitable for supplying blocks for the facing of the dam. In a general way, all of them are more quartzose than the average bluestone and some, therefore, are more nearly related to quartzites than to the simpler bluestones such as were used for the blocks in the Cyclopean masonry of the Olive Bridge Dam. There are no constituents that readily decay or develop stain or are likely to exhibit weakness. The mineral composition is as stable as the constituents of the best types of rocks.

The rock has a roughly granular structure and undoubtedly was a very granular accumulation when it was deposited. Microscopic examination, however, discloses that many of the original grains are fragments of rock rather than fragments of simple minerals, and, therefore, are complex in their own structural make-up and mineralogy, each fragment containing quartz, sericite, and sometimes chlorite. This fact makes the rock look more complex than the usual sandstone, but all the fragments are of durable, firm materials and no detrimental quality is introduced by the fact of their complex structure. It would be difficult to find better rock for exposed structures than the bluestones of the Catskills. Even a granite resists weathering no better, and some varieties of granite, because of their different structure, are not as durable.

Location of the Catskill Aqueduct

In the early investigations of a water supply for New York City, sources east of the Hudson River, as well as the ground-waters of Long Island, were considered. As these studies were extended, it became evident that the streams of the Catskill Mountains were the best available sources. A storage reservoir site of great promise was shown to exist at Ashokan, and rather early in the studies it became evident that the aqueduct must start from the Ashokan Basin. The problem was one of conveying a large quantity of water from the Esopus water-shed to New York City. It was also necessary to develop a considerable storage basin near the city, on the line of the aqueduct, and, for this, the Kensico Reservoir site was selected.

The region traversed by the aqueduct may be divided, for convenience, into the following districts:

(1) The elevated easterly margin of the Catskill Plateau, extending from the Ashokan Reservoir to the Rondout Valley;

(2) A part of the Great Appalachian Valley, extending from the Rondout-Esopus border of the Catskill Mountains to the Highlands of the Hudson;

(3) The mountainous Hudson Highlands;

(4) The Piedmont region of Westchester County, south of the Highlands, extending to Long Island Sound; and

(5) Part of the Coastal Plain, represented by Long Island.

Each of these types of country presented problems peculiar to its own structure and history, so that a great variety of factors is involved. The type of structure selected and economy required that as much of the aqueduct as possible should be constructed on the hydraulic grade, but where the country rises above the hydraulic grade, it was clear that such heights must be penetrated by tunnels at grade, whereas valleys or depressions could be crossed by pressure tunnels at considerable depth in sound rock.

Geologic Features Affecting Location.—The geologic factors entering into the location of the aqueduct take into account such large features as the structural basis and origin of the topography with its variety of relief forms, modifications of drainage, and changes in topography due to glaciation, the general structural trend of the formations, with their attendant folds, faults, joints, cleavage, and the general physical condition of the rocks of the region. All these geological factors contribute to an understanding of the present and former topography and the general rock condition and behavior of the ground. They affect, therefore, the general problem of location. For example, the Tertiary peneplain in its gradual descent from the inland country toward the sea practically fixes the hydraulic grade across the broad tracts bordering the Hudson River. In like manner, the trend of formational structure is in direct control of the courses of the valleys and ridges, and thus, also, governs the choice of possible courses the aqueduct might follow.

The first aqueduct route to be investigated began at the east end of Ashokan Reservoir near West Hurley, N. Y. Shortly after this line was surveyed, detailed studies showed that a change in the out-take of the reservoir from the location studied near West Hurley at the east end to a point near the Olive Bridge Dam had certain advantages in the operation of the aqueduct. In addition, the shifting of the line farther west made available certain topographic features favorable to its location. Investigations by borings in the Hudson River near New Hamburg, N. Y., early established the fact that the rock gorge there is very deep. Furthermore, on the New Hamburg route, a crossing of the Hudson Valley from the vicinity of Marlboro, N. Y., to the Highlands near Fishkill Village, would have required a pressure tunnel about 9 miles long, penetrating the limestone beneath the river. The uncertainties of behavior of the limestone under such conditions early led to suspicion of all lines along which these dubious formations were prominent. In addition, several faults would have to be crossed by such a tunnel, and it was believed that some of them might prove to be troublesome either in construction or maintenance. Consequently, attention was called to the possible advantages of crossing the stream between Storm King and

Anthony's Nose where the old crystalline rocks of the Highlands assured a much firmer medium for a tunnel and the avoidance of most of the uncertainties and known difficulties of the New Hamburg route.

Choice of the Storm King Line.—The work of exploration was finally concentrated at Storm King on the northern margin of the Highlands, where the river was narrow, the rock sound, and the conditions generally favorable for deep shafts. Preliminary to the adoption of this location, four lines were investigated, namely, the Storm King, the Little Stony Point, the West Point, and the Anthony's Nose lines.

The objection to the Anthony's Nose line was that a great part of the route through the Highlands would be in tunnel, with several deep shafts, in places far back in the hills difficult to reach, with a long pressure tunnel beneath the river itself. On the West Point line, although the river is only 2 100 ft. wide, the distance between hydraulic grade points is 1.6 miles. Furthermore, a wide crush zone and a belt of ancient limestones are believed to lie beneath the river, which was judged to be less favorable for tunneling than a more substantial rock. The Little Stony Point line had the disadvantage of requiring some cut-and-cover on the west side of the river, in glacial drift, along an exceedingly steep mountain side, where land slides of soft material might endanger the stability of the aqueduct. On the route finally chosen at Storm King, the river is 2 900 ft. wide, with excellent rock on both shores. Favorable and accessible shaft sites near the edge of the river were an important advantage in this location, and the "cut-and-cover" country on the east side of the river through Breakneck Valley made for additional economy. The determination of the depth to bed-rock under the river was a critical problem by any route, as that depth would control the depth of the pressure tunnel. It thus became practical to concentrate work at a definite point so that this investigation could be made. Boring operations for this purpose, in the gorge of the Hudson, were carried on for about two years. This location is described subsequently in more detail.

After the Hudson River crossing was once established, the route to the south of it became fairly well fixed, the first objective being Kensico Reservoir and the second one, Hill View. The controlling features were the topography of the region and the economy of the project. No sufficiently objectionable conditions were found to warrant great changes of course after it was once laid out. South of Hill View, however, within New York City proper, many alternatives were presented, which required detailed study and exploration. This part, which is known as the City Tunnel, is discussed subsequently in more detail.

Cut-and-Cover Aqueduct South of Ashokan Reservoir

From the main head-works of the Ashokan Reservoir at Brown's Station, N. Y., the aqueduct follows the post-glacial valley of the Beaverkill, along a drumlin, as a cut-and-cover structure as far as the gorge of Esopus Creek which cuts at right angles to the course of the aqueduct. On the north side of this gorge, a boring was made to determine the depth to the bluestone ledge which outcrops in the stream bed and across the valley of the creek to the south.

It was expected that this valley would be crossed by a pressure tunnel deep in the rock, but as the borings in the north bank showed that the bed-rock was deep and sloped downward to the north beneath the drift hills into the buried gorge of the pre-glacial Esopus, the plan for a tunnel was abandoned, as the down-take shaft would be in earth to a prohibitive depth. A steel pipe siphon, therefore, was adopted instead of a tunnel in rock, for the crossing of the Esopus trench.

An inspection of the topographic map, particularly at Elevation 500, shows that the south side of the Esopus Valley, for a distance of several miles south of Ashokan Dam, is much smoother and less broken by tributary gullies than the north side. This difference is due largely to the effect of glacial action in smoothing the south bank in the southwestward movement of the ice during the main ice advance, whereas the roughness of the north bank is due to the gullying action of the glacial waters discharging from the northeast into the Esopus gorge in the retreat or melting stage of the ice. Because of this greater smoothness of contour, the south side of the valley was chosen for the location of the aqueduct. The only considerable depression on this line for several miles is the gully of Tongore Creek near Davis Corners, N. Y., where a pronounced trench is cut in the glacial till by waters discharging from the drift-filled valley to the southwest. It was crossed, as in the case of Esopus Creek, by a short steel pipe siphon.

At the "Atwood Cliffs", still farther south, the aqueduct was carried along the face of the precipitous escarpment for 900 ft. with a deep cut in the rock. In the much jointed, horizontally bedded shales and bluestones of the Hamilton, which form the bed-rock in this section of the line, it was found that the explosives used shattered the rock so badly that the trench broke wider than had been expected, thus increasing the work involved, particularly where the surface material was affected considerably by weathering.

Peak Tunnel was driven through the bold hill at the point of leaving the Esopus Valley, thus making a short-cut course to the much smoother country along the edge of the Hamilton escarpment which forms the westerly margin of Rondout Valley. For the cut-and-cover portion south of Peak Tunnel, hard, well compacted, glacial till was encountered, which was successfully excavated to the narrow base and steep slopes prescribed, effecting a material saving over the wider trench in the horizontally bedded and weathered rock north of Atwood, N. Y. At the southeasterly end of this stretch of cut-and-cover construction, the Rondout Valley is reached, and a pressure tunnel in bed-rock was adopted for this crossing.

General Considerations Relating to Design of Pressure Tunnels

Of all the types of aqueduct, the pressure tunnel, perhaps, was given the most study, as there was no precedent for tunnels operating under such high heads. Pressure tunnels had been used to some extent, but none of them was subjected to an unbalanced head much greater than 100 ft., whereas on the Rondout Pressure Tunnel the unbalanced head is about 400 ft. and the ground-water head on the Hudson Pressure Tunnel is 1 100 ft. when the tunnel is empty. The pressure tunnels are designed with vertical waterway shafts and a tunnel deep in the rock to carry the water from one side of the

valley to the other. The strength and water-tightness of the rock is mainly depended on to retain the water without undue loss. The tunnel excavation, which is circular in form, is lined with concrete, to serve not only as a support to the rock and to provide a high coefficient of flow, but also to obstruct the escape of water from the tunnel. This last function of the concrete is aided by grout, which was forced under high pressure into all openings between the concrete and the rock and also into all water-bearing joints and porous openings of the rock itself, within reach of the operation. The concrete lining, therefore, supplemented by the grout filling of all adjacent spaces is depended on to make a reasonably water-tight conduit. The advantages of this type of construction may be enumerated as:

(1) Great permanence;
(2) Very low maintenance cost;
(3) Cheaper original cost than any other equally efficient conduit; and
(4) Convenience in operation.

The last two considerations may be illustrated by the 18 miles of pressure tunnel in New York City where sixteen lines of steel pipe of large diameter would have been required to carry and distribute a supply equivalent to the single pressure tunnel.

Permanence is a matter that has been most carefully considered. In the case of other pressure tunnels where relatively low pressures have been used, the rocks are stable and little disturbed by folding and faulting. In the country traversed by the Catskill Aqueduct, serious local movements have disturbed the strata, but the rocks are generally of such an insoluble and permanent character that there is little fear of their deterioration. This sound character of the rock is a decidedly favorable condition. It appears also that the lower New York region is now comparatively stable as compared with most of the Rocky Mountain or Pacific Coast regions. One must recognize that movement might occur here, or for that matter anywhere else; but few known regions have so little evidence of recent disturbance as this, although in an earlier period such movements were common and extensive. Some of the most important effects of these earlier disturbances may now be seen in the faults and crush zones encountered in many places. At such points, the rock is much weaker than usual and is also less stable during and after construction, and, furthermore, it is believed that if a new movement should affect the region, it would be likely to follow some of these old weaknesses. Therefore, the line with the fewest known faults is the most desirable, not only because of the wish to avoid bad ground, but also because of possible further shifting.

In order to prevent bursting of the tunnel subjected to high pressures, which would result in leakage and loss of water, it is essential that the rock be strong enough to meet the severe demand made on it. Therefore, a proper understanding of the condition of the rock became of prime importance. Zones of disturbance, or decay of the rock, and zones of weakness induced by deformation were carefully considered. It was deemed to be very important to place the tunnel at an adequate depth beneath the surface of sound rock in order to escape the influence of superficial weaknesses. There-

fore, in all cases, a cover of not less than 150 ft. of sound rock was provided, except for comparatively light heads.

The circular shape was adopted for pressure tunnels and permanent shafts, because of the external pressure to which they may be subject, in places, when the tunnel is under construction or out of service. The pressure from ground-water depends on the relative porosity of the rock and the concrete. Thus, with a tight lining and porous rock, the lining would receive nearly the full ground-water head; whereas, with a tight rock and an equally impervious lining, the lining would get little pressure. It was thought that porous or seamy rock would be made tight by grouting and that the rock itself would constitute the main reliance against inward or outward leakage. The lining of the tunnel was made of such thickness as to withstand the static ground-water head and the grouting pressure, and the grouting of all openings back of the concrete lining was depended on to cut off outward leakage. This provision is very important, as water can escape wherever it can enter a tunnel and in much greater quantities, because the unbalanced heads producing outward flow from the full aqueduct under pressure are much greater. Ground-water pressures of 200 to 475 lb. per sq. in. have been measured by means of gauges applied to grout pipes in the tunnels.

The Rondout Pressure Tunnel

The comparatively low Rondout Valley is crossed by a pressure tunnel 4½ miles long, which was driven from eight working shafts about 500 ft. below the general floor of the valley. The tunnel has an inside diameter of 14½ ft., and the concrete lining averages 22 in. in thickness. The excavation averaged about 10 cu. yd. per lin. ft.

Summary of the Rondout Problem.—The main problem presented in the study of the tunnel location related to the proper depth of the tunnel in the rock, which, in turn, was influenced by the location and depth of the pre-glacial drift-filled gorges, and the attitude of the several rock formations penetrated, especially the location, thickness, and inclination of the Shawangunk grit with reference to its intersection by the tunnel. General studies and explorations, made to determine the choice of tentative lines crossing the valley at a number of places between Hurley and High Falls, showed that the geological formations at the location chosen were less disturbed by folding and faulting than at any other part of the entire valley, and other considerations made the High Falls location the most desirable. A comparison of the cost of rock tunnels with the cost of pipe lines and other structures, showed the tunnels to be the cheapest, even with shafts more than 1 000 ft. deep and allowance for special construction in case unusually bad ground should be encountered.

Earlier exploratory borings in the valley at Hurley revealed the rock in the bottom of the same ancient valley at a depth of 70 ft. below sea level, and showed that it is overlaid by a layer of sand about 220 ft. in thickness. This valley, following the Hamilton escarpment along the easterly margin of the Catskills, is bottomed by the Onondaga limestone. The line was finally moved several miles farther south, beyond the reach of the Esopus proper,

where a much heavier drift cover badly obscures the topography of the rock floor. From a study of the outcrops, applying the recognized principles of erosion effects on dipping strata, it was expected that the borings on the crossing at High Falls would discover a gorge in a corresponding position along the westerly margin of the valley at the border of the Hamilton flag formation. This was indeed the case. In addition, another gorge was disclosed by the borings near the middle of the valley, deeply buried, and so masked by deposits of glacial drift that its existence is not indicated in the present relief.

The first general geological cross-section of the valley, however, based on surface indications, was a fairly close approximation to the structure finally developed in much more detail by the borings. Two buried pre-glacial stream gorges, and the fact that the rock in places was broken by faulting and was porous, controlled the depth of the tunnel. Near the east end of the tunnel, also, a fold involving the very hard Shawangunk grit made it desirable to place the tunnel so deep that it would pass beneath the grit and lie entirely in the more easily excavated Hudson River shale below.

The geologic complexity of this valley is due chiefly to the number and variety of rock formations, including many beds of limestone, shale, and grit, and to their folded and faulted condition. On these strata of different resistances to erosion, a topography consistent with the detail of the structure has been developed. Where the more indestructible beds, such as the Shawangunk grit occur, there are ridges, and where the less resistant beds form the floor, erosion has cut deeper and there are valleys. The relief features of the rock floor, chiefly erosion channels, represent the work of streams due to the uplift preceding the Ice Age. These minor features, however, are much obscured by the drift. It is these later channels, especially their great depth, that became critical factors in determining the depth of the tunnel. The following formations are penetrated by the Rondout Tunnel, the Hamilton flags being at the top on the west side of the valley, and the Hudson shales, the lowest of the series, being on the east side of the valley:

	Thickness, in feet.
Hamilton flags and Marcellus shales	700
Onondaga limestone	200
Esopus gritty shales	800
Oriskany sandstone (not separately developed)	...
Port Ewen shaly limestone, including the Oriskany transition	200
Becraft crystalline limestone	75
New Scotland shaly limestone	100
Coeymans limestone	75
Manlius limestone, including the Cobleskill, and the Rosendale and Rondout cement beds	100
Binnewater sandstone	50
High Falls shale, including thin limestone layers	75
Shawangunk conglomerate	300
Hudson River slates, thickness unknown, probably more than	2 000
Approximately	4 775

Factors Affecting the Tunnel Grades.—The tunnel profile was fixed by the following requirements:

(1) To pass beneath the buried Kripplebush Gorge, at the west side of the valley, with a sufficient rock cover;
(2) To pass safely under the buried Rondout Gorge, near Station 500, in the center of the valley;
(3) To avoid, as far as possible, the Shawangunk grit, in the Coxingkill syncline, at the east side of the valley;
(4) To pass through the porous Binnewater sandstone in as short a distance as possible;
(5) To drive up-hill at a high angle through the heaviest water-bearing members for the purpose of draining the water away from the heading;
(6) To avoid driving up-hill on grades of more than 2% where lower grades are possible; and
(7) To have the entire tunnel drain toward the sump at the drainage shaft near Rondout Creek.

These requirements were met by placing the northerly half of the tunnel at Elevation — 100 in the vicinity of the most porous strata. There, a 15% incline through the wet ground connects with the southerly half which was put at Elevation — 250 so as to keep the tunnel below the Shawangunk grit and in the Hudson River shales.

Question of Solubility of Limestones.—The question of the possible solubility of the limestones was considered with great care. Certain caverns, due to the solution of these limestones, can be seen at the surface, and others were indicated by the borings, and it seemed not improbable that many solution channels may have been formed in earlier times to considerable depth in both the Onondaga and the Helderberg limestones. Fig. 6 is a view in the Rondout Siphon Tunnel, which shows the solution effects on bedding planes of Helderberg limestone, causing wild breakage at "mud seams", requiring 7 ft. of concrete in the roof.

If these limestones, which have proven to be soluble when exposed to ordinary meteoric water circulation, should yield in the same way to the tunnel waters, not only would the concrete lining be subject to disintegration, but the supporting rock immediately outside of them might be, in part, removed and the escape channels enlarged, seriously increasing the loss of water from the tunnel. These considerations led to the tunnel being placed below the zone most affected by surface-water circulation, avoiding as far as possible the most susceptible strata. It led also to the rejection of limestone aggregate in the concrete lining.

Factors Affecting Construction.—Under the subject of design, the general condition of the rocks of this region and their structural relations have been discussed. The hard or soft character, porous or fractured condition, and resultant permeability, the chemical changes to which they have been subjected, all have a bearing on the methods of tunnel driving and the design of tunnel adopted. Although the rocks are mostly hard, durable, and sound, the earth movements to which they have been subjected have resulted in the

formation of folds, joints, occasional faults, and crush zones. Such conditions may result unfavorably by causing an unsafe roof in places, requiring scaling or the use of temporary wooden timber or even permanent steel roof support. In other cases, small folds or intersecting fracture planes produce blocky and caving ground. In the soluble limestones, the circulation of underground water tends to dissolve parts of the beds and to produce openings by the enlargement of joint planes, with the result that the rock is weakened and, in places, cavernous. Conditions such as these required enlargement of the excavation in unsound rock, reduced the speed of excavation and the placing of concrete, and, in a few places, introduced an added cost for steel or timber roof support.

Since the lining has been placed, an opportunity has been given to observe the effect of ground-water on the concrete. The concrete shows no tendency to deteriorate and tests of the aqueduct in service have shown the pressure tunnels to be tight against outward leakage.

The Rondout Pressure Tunnel affords a good illustration of the influence of underground conditions on the progress of tunnel work. Fig. 8 is a progress diagram of the Rondout Tunnel and illustrates the influence of adverse geological conditions on the progress of the work. Where the rock was fairly uniform in quality, as in the shales and limestones, rapid and consistent progress was made in excavating, the average progress in these rocks being 350 ft. per month. Because of the hardness of the rock, the progress in driving through the Shawangunk grit was much slower, averaging 160 ft. per month. The longest delay in the construction of this tunnel was at Shaft 4 and in the tunnel between Shafts 3 and 4. The difficulties there were due to the large inflow of water in the Binnewater sandstone and High Falls shale. Shaft 4 was flooded several times and the sinking of it was delayed about a year on account of the troubles caused by water. An account of the sinking of this shaft has been given in a paper* by John P. Hogan, M. Am. Soc. C. E.

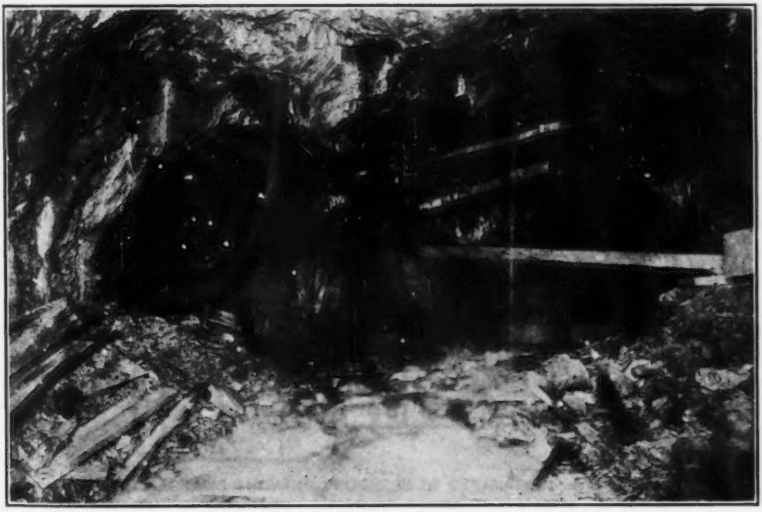
The large mud seams and broken cavernous ground encountered in excavating the tunnel south of Shaft 3 necessitated special methods in driving and lining. Special provisions were made there for reinforcing the tunnel with a steel shell. These extra precautions and the provisions made for curing the natural weaknesses caused much additional delay. Hydrogen sulphide gas in the Binnewater sandstone and High Falls shale made it difficult for men to work, as their eyes were affected by the gas, and to remedy this trouble, ventilation by blowers was provided. The acid water and gas also attacked the switchboard equipment of the electric pumps, making special protection necessary.

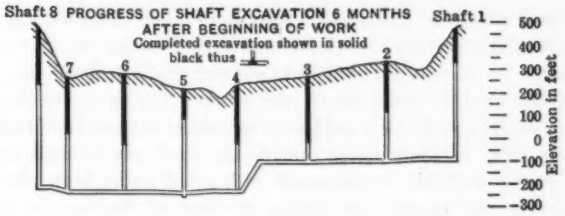
Fig. 7 is a view in the Rondout Pressure Tunnel, which shows the wet ground encountered in the High Falls shale and the Binnewater sandstone where these rocks were penetrated by the tunnel at the overthrust fault near Shaft 4.

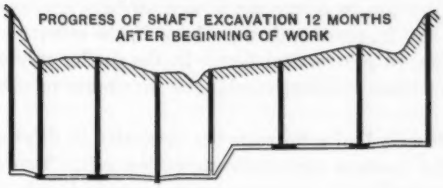
Although the water-bearing beds on the incline gave so much trouble, most of the water entered in a stretch only 175 ft. long, half way up the incline

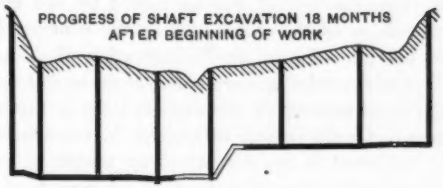
* "Sinking a Wet Shaft", *Transactions*, Am. Soc. C. E., Vol. LXXIII (1911), p. 398.

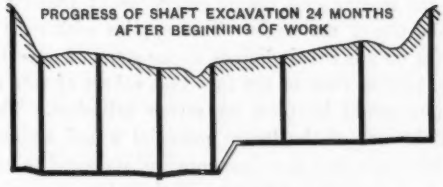
FIG. 6.—VIEW IN RONDOUT SIPHON TUNNEL, SHOWING SOLUTION EFFECTS ON BEDDING PLANES OF HELDERBERG LIMESTONE.











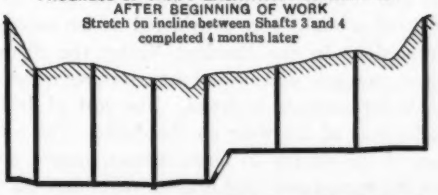


FIG. 7.—VIEW IN RONDOUT PRESSURE TUNNEL, SHOWING WET GROUND IN HIGH FALLS SHALE AND BINNEWATER SANDSTONE.

DIAGRAMS SHOWING PROGRESS OF EXCAVATION RONDOUT PRESSURE TUNNEL

The slow progress in sinking Shaft 4, and in excavating the Tunnel between Shafts 3 and 4, was due to (1) The excessive quantity of water encountered, (2) the effects of H_2S Gas and (3) the Crushed and Broken Ground Penetrated in the Tunnel.

FIG. 8.

in the High Falls shale, where these beds were much distorted along a strong thrust fault which seemed to furnish the way of escape for all the overlying porous beds. To prevent outward leakage from the tunnel which is subject at this point to a head of about 700 ft., the concrete lining was made 3 ft. thick. This lining was placed inside a steel shell to protect the concrete during placing and setting. Dry packing placed outside the steel was grouted and the surrounding porous rock was impregnated with grout under high pressure. The water entering the tunnel just before closing all leakage in this stretch amounted to 1 000 gal. per min. Ground-water was drawn down to Elevation — 55, and after all pumping was stopped, it took 40 days to restore it to Elevation + 65, a rise of 120 ft., representing a volume in the tributary underground reservoir of 64 000 cu. ft. per vertical foot. In the earlier stages of construction, the inflow was much heavier, reaching a maximum of about 1 900 gal. per min.

Although 250 000 cu. yd. of solid rock was excavated in driving this tunnel, none was suitable for concrete aggregate except the grit. Two quarries were opened in the Shawangunk grit outcrops situated east of Rondout Creek, making long hauls necessary in transporting the crushed stone to the several shafts. The rock excavated from the tunnel was examined by the geologists, who investigated the permanence of the stone used in the concrete lining of the deep tunnels and the possible solution or disintegration of the material composing the concrete. Their conclusions are summed up as follows:

The pressure tunnels are necessarily the weakest links in the whole Catskill System. They present not only special difficulties in construction, but they will be continuously subjected to greater strain by reason of pressures, and greater attack from the solvent action of water than other parts of the aqueduct line. If the work is to be permanent or even reasonably durable, every consideration affecting the matter as a public enterprise of importance is on the side of caution in the use of materials. This applies with most force to the pressure tunnels. Not only is it injudicious to use stone of uncertain or doubtful resisting quality, but, in view of the fact that others of safe character are available, such action would be open to severe criticism. The additional expense involved in the use of the better material would amount to such a small proportion of the whole cost as to lose much of its seeming importance.

The weak shales were condemned because of their low strength and marked tendency to dry out and crumble on exposure to the air. The limestones, although strong and hard enough, were considered as too susceptible to solution. Of all the formations in the Rondout Valley the Shawangunk grit, because of its hardness, strength, and insolubility, was regarded as the best of the local rock available for concrete material. The cost of drilling this very hard rock was high, because of the wear on the drills. The rock is strongly bound, and came out of the quarry in large masses, jagged and difficult to handle. The wear on the manganese steel crusher parts exposed to the cutting action of the hard quartzites was great, and renewals were frequent.

Failure of the Rock Under the First Hydrostatic Test.—After the tunnel had been completed, and the construction shafts sealed with concrete plugs,

the tunnel and end shafts were filled with water and subjected to the working pressure. Under this test the concrete lining was ruptured for several hundred feet between Shafts 3 and 4, making repairs necessary.

The tunnel lining had been cracked where the cavernous ground in the Helderberg limestones had been encountered, and also on the incline in the Binnewater sandstone. The limestones in particular had been weakened by solution along joints and bedding planes. These caverns and mud seams are not isolated, but are doubtless connected and irregular, following the pattern of the original joints. Evidently, the pressure in the tunnel had overcome the resistance of the surrounding rock, which was not everywhere solid and continuous, but in effect had become, in some places, a series of blocks separated by soft and yielding clay. It was necessary, therefore, to repair the damage and make the tunnel water-tight. Steel shells had been used originally at certain points of well recognized rock weakness, and at none of these places was there any movement or damage. Accordingly, it was decided to repair about 700 ft. of the cracked tunnel in a similar manner. This was done in three stretches by reinforcing the lining with a steel shell about 1 in. thick, made up of rings composed of 15-in. channels with their flanges riveted together. The cracks in the rock caused by the movement of the ground were then grouted under high pressure, to prevent the escape of water. This repair was successful and no further difficulty has developed. When the tunnel was designed, the possibility of such failures was recognized, but it was thought better to discover points of weakness by test, and to strengthen those parts that required it, than to reinforce all parts of the tunnel about which there might be some question.

The Wallkill Valley

From Shaft 8, the terminus of the Rondout Pressure Tunnel at the western slope of the Shawangunk Mountain, the aqueduct pierces the mountain about Elevation 450 by a tunnel which is driven in the easily excavated Hudson River shale beneath the cap of hard grit covering the north end of the mountain ridge. This tunnel emerges below Bonticou Crag on the east slope at a favorable point for a portal. A tunnel through this mountain at any other location would have been much longer, or would have encountered the resistant grit bed, in either case greatly increasing the difficulty of driving and the cost.

Freer Cut.—On the eastern slope of the Shawangunk Mountain (Fig. 9), where the rock ledges are sparsely covered by glacial drift, the aqueduct follows the contour southward at grade for a distance of 4 miles. Here, the excavation encountered the shales of the Hudson River series which were excavated rapidly and cheaply by blasting and steam shovels, except in the deep Freer Cut, where difficulty was encountered through a stretch of 2 000 ft. The strike of the rock formation here is nearly parallel with the center line of the aqueduct and the dip is about 40° in the direction of the general eastward slope of the mountain. (Fig. 10 is a view of the cut-and-cover aqueduct in Freer Cut, in the Hudson River shale, which shows wide breakage due to the dip of bedding planes at the west (right) side (1:1 slope). Note the steep slope (6:1) of the cut on the opposite side).

Trouble was had from the beginning on the west side of the Freer Cut by the sliding of the rock on its bedding planes. As the cut increased in depth, the shale slid down in great masses into the cut, burying the track and steam shovel. The right or east side was self-sustaining, because the dip of the beds on that side was away from the excavation. The greatest single slide amounted to about 2 000 cu. yd. of rock. Because of the great widening of the cut on the west side by these slides, it was necessary to re-locate the aqueduct structure after the excavation had been in progress for some months, moving the center line to the east so as to keep the excavation within the property lines of the city. The contractor's railroad for the stone supply from the quarry at Bontecou was also affected, and was rebuilt for a distance of several thousand feet. The conditions at Freer Cut increased the excavation from an estimate of 85 000 cu. yd. to 155 000 cu. yd. actual, besides requiring a substantial modification in the design of the concrete structure, in order to avoid possible damage.

Geology of the Wallkill Valley.—The Wallkill River is a striking example of a retrograde stream. It flows northeasterly from its source in New Jersey a total distance of about 75 miles in a direct line, to the southward-flowing Hudson which it joins at an obtuse angle. This fact alone is sufficient to indicate that its present channel is composite, and that a part of the drainage has been reversed in comparatively recent geologic time. A reversal of the drainage means that the modern river is at some point flowing across a former divide or water-parting; and the approximate location of this divide, if it is not too far from the normal course of the aqueduct, is of practical importance, as it would furnish a crossing with the highest possible rock floor and the least gorge development. The determination of the latitude of the buried divide and the location and depth of the pre-glacial gorge were given special study.

North of the New Jersey boundary, the geological structure of the Wallkill Valley is as simple as that of the Rondout Valley is complex, because from this section of the Great Valley, erosion has removed the entire series of Silurian and Devonian strata down to the Hudson River slate and sandstone. On the northwest, the Hudson River slate rises in the steep slope of Shawangunk Mountain capped by the heavy protecting bed of Shawangunk grit. Much of the floor of the Wallkill Valley is referable to the Tertiary base level; but north of New Paltz, N. Y., the immediate or inner valley of the Wallkill, 1½ or 2 miles wide, close to the base of Shawangunk Mountain is sunk below this level. To this inner valley, the Tertiary peneplain holds the relation of a broad uneven terrace stretching between it and Marlboro Mountain to the east. The Hudson River beds are, throughout, strongly folded and characterized by a marked cleavage structure dipping to the east. Throughout the area of the Hudson River formation, there is less agreement between the topography and the geological structure than with the other strata, but even in this series, wherever marked differences of hardness exist, this fact is reflected in the topography.

The absence of much boulder clay in this part of the valley greatly facilitated the making of test borings. South of Libertyville, N. Y., however,

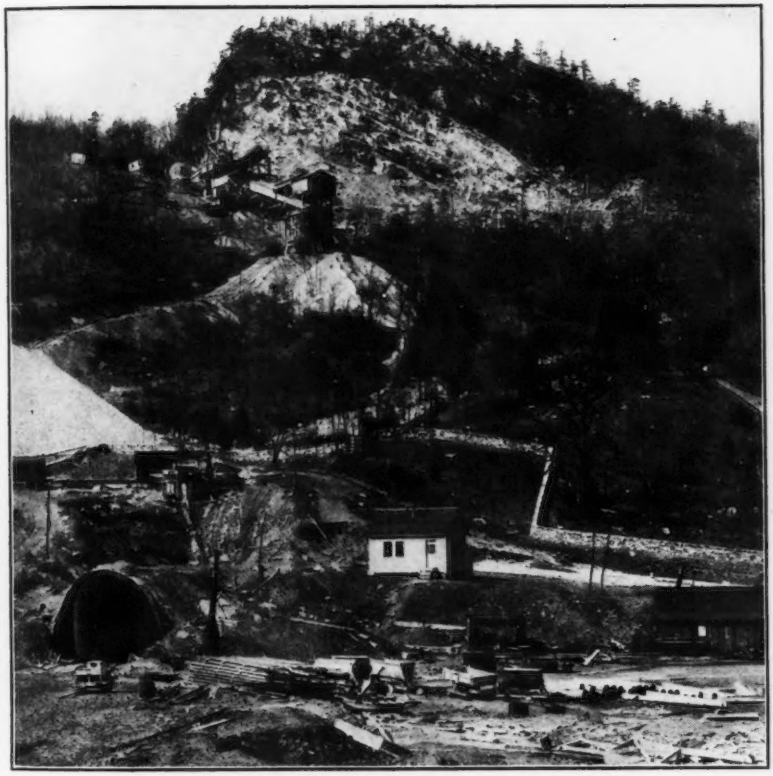

FIG. 9.—GRADE PRESSURE TUNNEL EMERGING BELOW BONTECOU CRAG, ON EASTERN SLOPE OF SHAWANGUNK MOUNTAIN.

FIG. 10.—VIEW OF CUT-AND-COVER AQUEDUCT IN FREER CUT.

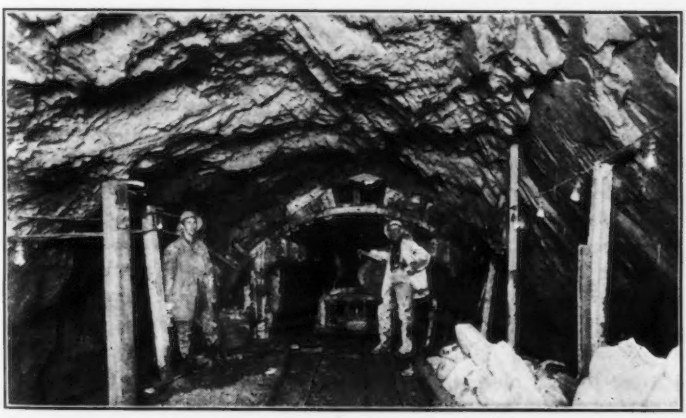

FIG. 11.—VIEW IN WALLKILL PRESSURE TUNNEL, SHOWING STRUCTURE OF HUDSON RIVER SHALE. CONCRETE ARCH FORMS IN BACKGROUND.

the drift is largely boulder clay for about 8 miles, to the vicinity of Walden, N. Y. The favorable character of the Hudson River shales for aqueduct tunnel construction was always recognized, because of the sound unweathered condition of these sandy mudstones. Although folded and faulted considerably, they are largely self-healing and tight, even along zones of strong movement. Almost the only purpose of the borings was to determine the position of the bed-rock floor and the depth and position of the buried pre-glacial channel of the Wallkill. The first and most northerly line of borings was made at Springtown, N. Y., where the old buried bed-rock gorge was found near the Wallkill Valley Railroad Bridge and was shown to be at a depth of 270 ft., extending 79 ft. below sea level. Southward, the elevation of bed-rock in the old stream bed rises rapidly until, at Libertyville, the bed-rock floor was at Elevation 67, or a rise of 147 ft. in 5 miles, an average of about 30 ft. per mile.

Design and Construction of Wallkill Pressure Tunnel.—The design of this tunnel was simplified by the fact that the rock to be penetrated was entirely Hudson River shale of almost uniform character. It was not necessary to consider, as in the case of the Rondout Tunnel, the rates of excavation progress to be expected, and the difficulties to be encountered in various broken and porous formations. The principal consideration in establishing the depth below the bed-rock surface was to provide adequate rock cover along the entire length of the tunnel.

The probable depth to which the rock might be decomposed and the general strength of the rock as it lies in the ground were also regarded as of prime importance. This kind of rock is not deeply affected by weathering, and although the ground-water level was doubtless much lower in pre-glacial times, there is no evidence that the rock was materially weakened except superficially. The ice sheet removed nearly all the loose and decomposed rock of that time, leaving the surface generally fresh and polished. This shale formation may be regarded as generally rigid enough to sustain itself and yet sufficiently yielding to make many open seams or joints improbable at the depth of the pressure tunnel. The great body of gravel and sand filling the main part of the buried gorge is indicative of a large water storage and suggests caution. Even so, a cover of 150 ft. of slate would seem to afford ample protection to the tunnel, because at this deepest point the rock is likely to be exceptionally fresh and sound.

The tunnel was accordingly designed with a pump shaft in the rock, with a minimum depth in earth, just east of the buried gorge, for convenience in discharging the drainage into the Wallkill River when emptying the aqueduct. The tunnel grade beneath the lowest point of the bed-rock of the pre-glacial gorge was covered by 150 ft. of bed-rock. The drainage shaft for the Wallkill Tunnel was placed near the Wallkill River and the spacing of the five other shafts was balanced in accord with this location of the drainage shaft. Although six shafts were sunk for this 4½-mile tunnel, eight of them were found to be necessary for the more complex conditions at the Rondout Tunnel, which was about the same length.

The general uniform quality and attitude of the thin beds of the Hudson River shale, together with the absence of open joints or porous beds carrying

heavy flows of water, made for comparatively rapid progress and low expense in the construction of the Wallkill Tunnel. The contract price per linear foot in the Wallkill Pressure Tunnel, including shafts, was $146.31, compared with $248.46 per lin. ft. in the Rondout Pressure Tunnel. This difference in price was due mainly to the difference in the geologic structure in the two valleys. Fig. 11 is a view in the Wallkill Pressure Tunnel, showing the prevailing structure of the Hudson River shale and its habit of breakage in the tunnel excavation. Concrete arch forms may be seen in the background.

The only hard rock encountered was for a distance of several hundred feet near the south end of the tunnel. It was very hard quartzitic sandstone, and it required from 20 to 24 hours to drill the heading as against 4 to 5 hours in the shale. The water encountered during the excavation of this tunnel amounted to 500 gal. per min. entering through joints, with no great flows at any one place. It was noticed that the inflow remained about constant for the entire siphon during the working period. This was supposed to be due to the great depth of the tunnel below ground-water level, so that at no point was the water-table depressed to the tunnel level, and also because there was slow circulation and no abnormal conditions.

As the Hudson River shale from the tunnel was not considered a satisfactory aggregate for concrete, the specifications excluded its use, and the contractor opened a quarry in the Shawangunk grit at Bonticou Crag, at the north end of the line, the nearest source of concrete stone. This quarry proved to be an expensive source as it was situated high on the steep slopes, making access difficult; there was no level bottom for loading cars; the steep down-hill dip of the grit strata made it difficult to operate drills; and the hard and abrasive quality of the quartzite caused rapid wear in drills and crushers. The sand for the concrete was secured from the Rosendale sand plain near the Wallkill Valley Railroad track, a haul of 9 miles. Sand deposits near the line of the tunnel were explored, and although the material was generally coarser than the fine water-washed Rosendale deposit, it contained enough fine material to make it necessary to remove the silt by washing.

Hydrostatic Test.—When this tunnel was first filled with water to the hydraulic grade, the outward leakage was about 1 100 gal. per min. This leakage rapidly diminished and, after several years, it became as low as 30 gal. per min. for the 4½ miles of tunnel, the reduction being due probably to the closing of the fine seams in the slate. When the first test was made, the water came to the surface at several places, particularly from drill holes which penetrated to the tunnel level. These holes formed active springs between Shafts 1 and 2, and softened the drift for considerable areas, but they finally ceased to flow.

Cut-and-Cover Aqueduct in the Wallkill Valley

The Tertiary peneplain on the easterly side of the Wallkill Valley is an open gently rolling country, the average elevation of which adapted it for the construction of the aqueduct in open cut for a distance of 22 miles, extending

from the uptake shaft of Wallkill Pressure Tunnel to the northwest margin of Moodna Valley which is also crossed by a deep pressure tunnel. Through this intervening upland, which forms a base-leveled divide, the deposits left by the glaciers presented favorable and easily excavated materials for the aqueduct trench. In these 22 miles, there were only two deep and heavy cuts, although the line is remarkably direct. Such a condition is due to the perfection of the base leveling or planation in Tertiary time, that is, the wearing down of the country to a plane, due to the long continued and unchanging level with reference to the sea.

Throughout the stretch, the prevailing material overlying the Hudson River shale is compact, glacial till, frequently requiring the use of explosives, except for 3 miles at the northerly end, between Ireland Corners and New Hurley, N. Y., where the east side of the valley is covered with kame deposits, evidently laid down while the center of the valley was occupied by a mass of ice. For 3 miles the aqueduct trench was excavated in this washed gravelly drift, as far south as New Hurley, where the line swings to the eastward, leaving the soft deposits and continuing south for many miles in hard glacial till. This difference in quality of materials affected the type of construction, the compact drift proving the more economical in cost of construction. For example, at the north end in the loose, water-deposited ground, an aqueduct with a wide base was required, and the payment lines for excavation were fixed on a slope of 1:1; whereas, in the solid ice-compacted till to the south, the structure was built with a narrower base and the trench was excavated to side slopes of 6:1. The cost per foot of the completed aqueduct in the modified or loose drift was $58.73, whereas in the adjacent compact glacial till, the cost was $48.06 per ft.

The Moodna Tunnel

Before it was decided to cross the Hudson River somewhere within the Highlands, there had been no Moodna problem. A crossing in the open valley region such as that originally proposed farther north at New Hamburg, would have avoided the whole Moodna section. As soon, however, as the crossing of the Hudson became fixed so much farther south, the line of the aqueduct was thereby established, approaching the Highlands on the west side of the river, and the crossing of the Moodna Valley assumed considerable importance. The Moodna is a comparatively small stream entering the Hudson just north of the Highlands, with its lower course lying across the most direct aqueduct line. The nature of this tributary, together with the character of the material through which it flows, suggests considerable drift filling.

By the time this problem came to be considered, it was known that the Hudson itself was very deep, several hundred feet at least. It seemed reasonable, therefore, to expect that a tributary such as this would have cut down to a somewhat similar grade. It was also appreciated from the studies of the Wallkill Valley, that the pre-glacial Moodna had probably been a larger stream draining some of the present upper Wallkill territory. In that case, the ancient Moodna must have been a more important stream than

the present one and probably had a somewhat different course. All this argued for a valley or gorge of much greater prominence than the present surface channel, but what its forms and profile was, no one could tell. The alternative Hudson River crossings in the Highlands involved corresponding changes in the location of the Moodna Tunnel, the lines farther south allowing the Moodna crossing to be located farther up stream. The Storm King crossing, however, which was finally adopted, gave preference to a line across the Moodna at its farthest down-stream position and permitted comparatively little chance for shifting.

It was planned at first to reach the Highlands margin with a pressure tunnel and to connect with the Hudson River Tunnel by a cut-and-cover aqueduct at grade along the northerly face of Storm King Ridge. It was finally decided, however, to construct the Moodna Pressure Tunnel on a more direct line and to continue at a suitable depth the entire distance to the Hudson River. This plan made it desirable to locate the tunnel as far to the north, down stream, on the Moodna, as natural conditions would permit, and explorations were conducted to determine the facts in detail. The early borings were rather widely spaced, but they soon disclosed that the deeper valley floor was abnormally flat for a distance of at least ½ mile and was covered with 300 ft. of very bouldery drift. Such a profile raised much speculation, the opinion prevailing that considerably greater irregularity probably existed than the borings had yet revealed.

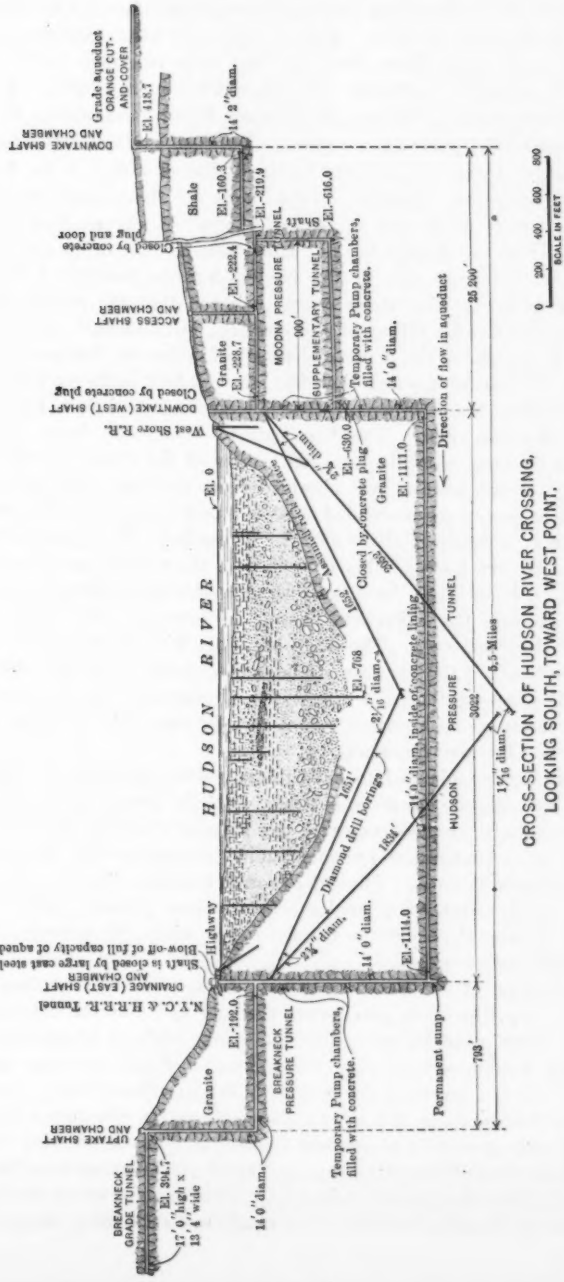
It was known at this time that the gorge of the Hudson was from 500 to 600 ft. deep, and, as the floor of the Moodna Gorge, only 2 miles distant, was shown by the borings to be only 50 ft. lower than the present water level of the Hudson, the argument was felt to be strong in favor of a deeper inner notch somewhere in the Moodna Valley floor. The borings showed that there could be no notch in the floor wider than 200 ft., and it was decided that a very deep canyon need not be considered. It is surprising to find so flat a valley bottom at this elevation, in view of the fact that the Hudson Gorge is at least 700 ft. deeper only a short distance away. The stream ought to have cut a deeper notch within this bottom. It is probable that at least two causes unite to develop this abnormally flat form. Glacial scouring doubtless aided, and, probably, also the ancient course lay more nearly parallel to the line of borings than that of the present Moodna. On the whole, however, the Moodna profile appears to be the most abnormal of any on the aqueduct line.

It was necessary to determine the character of the rock of the valley floor, in addition to the depth of the gorge, but this of itself did not require a very extensive series of borings. It was easily found that the chief formation was the Hudson River shales and sandstones and that although beneath them and above the basal gneisses, there must be 1 000 ft. of limestones and 500 to 600 ft. of quartzite, only very short stretches of tunnel would penetrate either formation. No quartzite was encountered in the tunnel excavation and only about 200 ft. of limestone. At places where these formations would normally be expected, they have been cut out on the

tunnel line by faulting. Only one stretch of ground exhibited a change in formations or any unusual structural relation. It was discovered in one of the earlier borings that crystalline rock like that of the Highlands occurred in the floor of the Moodna, under the deep cover of drift, but the adjacent borings showed only Hudson River sandstones and slates. Normally, the quartzite and limestone should lie between, but no such occurrences were discovered.

When the tunnel was driven, it was found that the stretch of crystalline rock was less than 200 ft. wide, that it was bounded on both sides by fault crush zones in which the rock was so weak that it required timbering, and that the formation immediately in contact on both sides is Hudson River shale. Undoubtedly, this crystalline strip is a remnant left stranded after two periods of faulting, and it is reasonably certain that it does not extend up from the granite basement, but instead is completely cut off below by these two faults. Doubtless, it would be possible, at somewhat greater depth, to pass beneath such a block as this and not encounter the granite.

The Great Thrust Fault.—At the margin of the Highlands where the tunnel line passes from the Hudson River slates and associated rocks to the Highlands granites and gneisses, the transition is sharp. A short distance north of the line, limestone may be seen along the contact within a few feet of the granite. A short distance south of the line, the limestone does not appear, but slate lies near the granite contact. North of the line, ½ mile or more, slate and granite can be seen in contact with a crush zone strongly developed and with the crystalline rock lying above the slate, the contact plane dipping at an angle of approximately 45° toward the Highlands beneath the granite. This represents an overthrust fault, the granite having been pushed up over the slate on a 45° plane.



Borings placed so as to develop this structural condition at depth indicated the same fault on the tunnel line and with about the same angle of dip. When the tunnel was constructed, the fault was encountered as indicated. At that depth, however, about 200 ft. of limestone intensely crushed and rehealed, and so deformed by that process that its bedding could nowhere be determined, was encountered. On the west side of the limestone, the Hudson River formation continued and beyond the fault to the east only granite was found. The rock was badly crushed and slickensided and sheared in the vicinity of the granite, and a similar crush zone was developed at the contact between the Hudson River slates and the limestone 200 ft. farther west. Except at the two more pronounced crush zones referred to, the ground in the tunnel was good and sound for construction purposes and required no special or unusual attention. The great fault at this point which probably represents a displacement of 2 000 to 3 000 ft., and perhaps more, is crossed by the aqueduct without any structural difficulty. The cost of construction per linear foot of this tunnel was the lowest of any pressure tunnel on the aqueduct. It is evident from the success of the pressure tests and later operation that the depth of the tunnel is adequate and that no danger exists, due to structural weakness of the rock or to erosion notches, of sufficient consequence to interfere with the success of operation and permanence.

The Hudson River Crossing

A great number of factors were involved in fixing the location for crossing the Hudson River, some of which involve advantages of aqueduct location through the intervening country between the Catskills and the Highlands and others which apply in equal measure to its southerly extension toward the city. The vital and decisive factor, however, in selecting the exact location concerned the geological conditions at the crossing itself.

The possible places for crossing may be divided into two groups. One known as the "New Hamburg group" included all the crossings considered in the territory north of the Highlands where somewhat metamorphosed and badly deformed sedimentary rocks of the Cambro-Ordovician Age, including shales, slates, limestones, and quartzites, constitute the formations through which the tunnel would have to pass. The other known as the "Highlands group" represented the possible crossings within the limits of the Highlands. This Highlands region is characterized by crystalline rocks, including chiefly granites and gneisses of considerable variety, more or less disturbed by deformation, but, in general, comparatively sound. The New Hamburg group was explored sufficiently to determine that there would be a long pressure tunnel where limestone would be encountered under conditions encouraging to structural weakness. This ground north of the Highlands is known to be badly disturbed by faulting, and these conditions could not be avoided. It is a good general principle to avoid such objectionable weaknesses if it can be done, by locating in ground of more favorable quality. On this account, in large part, the Highlands group of crossings came into additional prominence. They avoid the weakened and deformed sedimentary series, except in so far as they would be encountered in crossing the Moodna Valley.

The several possible lines within the Highlands were further studied for individual differences. When the locations were studied in detail, it was found that the most southerly lines, especially the West Point line and any possible line farther south, would cross a large fault and crush zone under the Hudson River. It was also certain that all the southerly lines would cross much more varied rock types, and it was considered desirable to avoid this complication. Accordingly, the Storm King line at the extreme northerly margin of the Highlands was finally adopted as the best location. It was the opinion of the geologists that the whole section could be constructed at this point through granite of a single type from one side of the river to the other without crossing any major structural weakness; whereas an equally favorable combination of conditions could not be found elsewhere. It was recognized at the outset that the depth of the river gorge was not known and perhaps would be difficult to determine. This was also true of all other points. It was recognized that this particular location, by reason of glacial action, might be unusually deep. This seems to be fairly certain since the final explorations were made, but the argument in favor of the Storm King crossing was not offset by any of these considerations, because of the great advantage of locating this critical section of the aqueduct at a place where the major uncertainties of rock quality and structural weakness were reduced to a minimum.

CROSS-SECTION OF HUDSON RIVER CROSSING, LOOKING SOUTH, TOWARD WEST POINT.

Fig. 12.

Preliminary explorations were made on all the lines before the final choice of the Storm King location. Subsequently, extensive explorations were conducted on the Storm King line. Borings were put down in the river under extremely difficult conditions and to extraordinary depth. Fig. 12 is a geologic cross-section under the Hudson River, and shows the deep preglacial drift-filled gorge in the granite, the deep shaft and pressure tunnel of the Catskill Aqueduct, and the inclined diamond drill holes for exploring the rock before the question of the depth of the tunnel was decided. A depth of 768 ft. below the surface of the water was reached in the middle of the river by the deepest boring, which even at that depth did not reach the rock floor. At each side of the center, borings penetrated 500 ft. before reaching rock. At this stage it was believed that the results obtained had demonstrated the feasibility of the crossing, but sufficient data had not been secured to determine the depth and detail of design so that construction could proceed. It was determined, therefore, to sink test shafts on both sides of the river and from them to explore the underground conditions by inclined drill holes under the river. The first pair of holes, one from each side, was projected so as to reach beneath the center of the river at a depth of about 1 400 ft. Sound granite was obtained from the cores for the entire depth. After these holes were completed, a second pair was projected to cross beneath the river at a depth of about 950 ft. These holes likewise penetrated sound granite. On the basis of this information, the tunnel was placed at a depth of 1 100 ft. below river level, and was constructed without special difficulty.

The Hudson River Pressure Tunnel is located at the north edge of the granitic Highland area. The large building, Fig. 13, near river level marks the East Shaft, 1 100 ft. deep. The buried gorge is nearly 800 ft. deep to rock. The top of the hills marks the Cretaceous peneplain or base level, whereas the inner rock terrace, which may be noted about 100 ft. above water level, is the Tertiary peneplain.

It was at first planned to have the aqueduct approach the Hudson River section at hydraulic grade connecting with the tunnel under the river by a down-take shaft. Later studies of the Moodna crossing, however, led to the adoption of a continuous pressure tunnel connecting the Moodna, Hudson, and Breakneck Tunnels. Thus, the tunnels constituted one system at different levels. At the connecting angles between these pressure tunnels, structural weaknesses later developed in the solid rock when full pressure was applied, and repairs were required.

No faulting of any consequence was discovered in excavating the tunnel. Two or three slips were noted near the east end, but the original judgment that the river could be crossed at this point without penetrating any great structural weakness such as a crush zone or fault line was substantiated. In certain zones, however, the rock is under unrelieved strain, still preserved from the deformations of earlier geologic time. In the deeper workings, this strained rock at certain places had a tendency to scale off with violent explosions. Sometimes this scaling happened suddenly, breaking from the wall where previously the rock appeared to be sound. This scaling, which was known to the workmen as "popping rock", was encountered at several places and also in

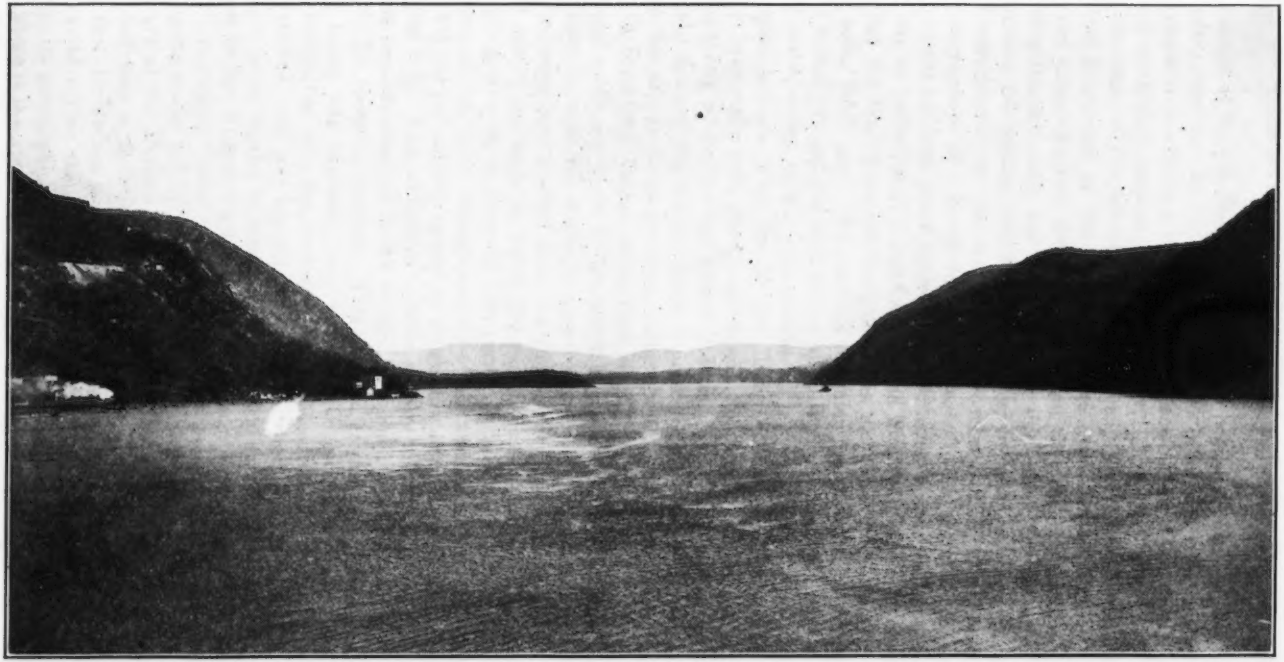


FIG. 13.—LOCATION OF HUDSON RIVER PRESSURE TUNNEL.

other tunnels of the aqueduct, but nowhere did it give as much concern as at the Hudson crossing. This condition of the rock is believed to have developed the weakness in the Hudson River end of the Moodna Tunnel after full pressure was established, making repairs necessary.

At one stage of the construction an unusually heavy flow of water from the joints penetrated by the tunnel near the east shaft required a large emergency pumping plant; the small equipment that had served successfully in sinking the east shaft was inadequate for the sudden flow of water just after turning the heading under the river. Fear of water had been expressed in the consideration of the tunnel project beneath the Hudson, and this sudden appearance of a heavy flow was thought to be ominous. However, after the joint had been closed by grouting, no further trouble was experienced. There was no indication of a direct connection with the Hudson River water itself and the large pumping equipment was not needed, the tunnel, as a whole, being fairly dry. The quantity of water for the 3 000 ft. of tunnel did not exceed 110 gal. per min. at any time after passing the inrush of the ground-waters stored in the joint system.

Moodna Repair.—When the Moodna-Hudson-Breakneck Siphon was subjected to hydrostatic tests, leakage developed. Subsequent examination showed that the lining of the Moodna Tunnel had ruptured at its junction with the down-take shaft of the Hudson River Tunnel and that water escaped to the surface through joints in the rock. There were, also, some cracks in the lining in Breakneck Tunnel at the river shaft.

Special study was given to the probable cause of this unexpected weakness where the rock had originally appeared to be sound and without water. The conclusion was reached that the rupture developed where the tunnel crossed one of the zones in which the rock is under strain. If penetrated at a little greater depth, it would have produced "popping rock", such as has been encountered in the deeper portions of the tunnel beneath the Hudson. Perhaps it was not unstable enough at the shallow depth to break without some additional help. This additional impetus appears to have been given by the bursting pressure supplied by the water-filled tunnel, when the rock was subjected to the operating pressure. This unstable ground then yielded and the tunnel lining was ruptured, thus allowing the escape of water into the joints connecting with the surface. On the Moodna side, therefore, where this disturbed zone was apparently several hundred feet in width, it was decided to make repairs by abandoning about 900 ft. of the Moodna Tunnel adjacent to the Hudson Tunnel and constructing a connecting step 400 ft. deeper. Rupturing under similar conditions was elsewhere corrected by caulking the cracks and by grouting.

Nature of the Hudson Gorge.—Because of its great depth, the Hudson Gorge has been a favorite topic for geologists and engineers. It is well known that the Hudson is a very ancient river and that at one time the Continent stood higher than it does at present. Under such conditions, the river cut its gorge, which can be followed by soundings nearly 100 miles out to sea where it is a veritable canyon from 3 000 to 4 000 ft. deep.

Knowledge of these conditions, together with the fact that hitherto no explorations had determined the exact depth of the gorge anywhere along its course below Albany, N. Y., gave especial uncertainty to the problem when the work first began. Later explorations have tended to show that although the Hudson River is very deep, more than 300 ft. at New York City, yet there are certain abnormal features of the gorge at the Storm King crossing that invite comment and require some additional explanation. The Hudson Gorge at Storm King is too deep and too wide to be wholly consistent with the cross-sections at other points. In its deepest part, below 300 ft., it is wider than at New York City, and it is known to greater depth. It is this fact, however, of greater width below the 300-ft. level, even though the rock is more substantial, that leads to the conclusion that the gorge has been "over-deepened" and enlarged by the glacial ice at the entrance to the Highlands. This is one of the clearest cases in the region of glacial over-deepening and enlargement. Probably nowhere else along its course is the Hudson so deep. The ice seems to have crowded into this notch between Storm King and Breakneck Mountains, gouging out the rock considerably deeper than it had been cut by the river itself. It appears, therefore, that the Storm King crossing may have required a somewhat deeper tunnel than would have been necessary at some other location, but it had other advantages quite offsetting this factor, and it was on these that the choice was based.

Special Features in the Highlands

The aqueduct through the Highlands comprises a succession of grade tunnels, cut-and-cover aqueduct, and steel pipe siphons. A variety of geological conditions was encountered, which were chiefly of scientific interest but which had some bearing on the original questions of location and design.

At one place in Foundry Brook Valley, a crush zone was encountered, which, at first, caused some concern, because the drill recovered only what appeared to be sand, but which proved later to be crushed and decayed material. This zone also carried much water, and one of the borings that penetrated it furnished an Artesian flow, which later was made the basis of a special claim for enhancement in the value of the land taken by the city. Another section of unusual character and local importance was in Garrison Tunnel, where a long stretch of residual decayed rock was encountered at the north end. It was assumed in the original survey that the rock which was a variety of gneiss, would be comparatively sound. In excavating the tunnel, however, a patch of pre-glacial residuary decay material was found at the north end beneath the drift, which the glacier had failed to remove. This gave trouble when excavated. A fault zone in the middle of the tunnel showed similar disintegrated material, but did not cause much trouble.

Sprout Brook Valley was thoroughly explored, but on account of the depth required for a tunnel, a steel pipe siphon was adopted as more economical, although a tunnel is feasible as far as geological conditions are concerned.

Fig. 14 is a view of the steel pipe siphon across Sprout Brook Valley. The valley is eroded on a narrow band of crystalline limestone with granite hills

on each side. The bottom of the valley is filled to a depth of 100 ft. with glacial drift. The opposite hill is penetrated by the aqueduct tunnel (Cat Hill Tunnel) for ½ mile.

In Peekskill Valley, the formations previously encountered on the north side of the Highlands were found to be closely folded, and affected by weathering and decay to a considerable depth. After exploration sufficient to map the occurrence, attitude, and condition of these formations, the steel pipe siphon was adopted as the method both for avoiding a deep pressure tunnel and some of the uncertainties of behavior of these rocks. Similar problems were encountered at numerous places where either small grade tunnels or short pressure tunnels were constructed.

Kensico Dam

At Valhalla, N. Y., a short distance north of White Plains, within about 20 miles of the city, it was decided to locate a storage reservoir. This is the site of the old Kensico Reservoir that was already a part of the New York City System, storing the waters of the Bronx River. However, in order to serve its purpose in the Catskill Project with a storage adequate for a three months' supply, it had to be greatly enlarged, and the geologic problems of this work were those incident to the greater importance of the high dam necessary for the increased storage.

At Kensico, the valley is comparatively narrow and deep, and its sides are rocky, although the bottom is filled with drift. It was known from the outcrops in the vicinity that the rock formation of the west side of the valley, at this point is Manhattan schist, that the east side is granite gneiss of considerable variety belonging to the so-called Fordham gneiss series, and that the Inwood limestone formation must lie in the bottom of the valley. It was evident, therefore, that the dam would stretch across the three important formations of the region, a fact which, in itself, would present no particular disadvantages unless unusual weaknesses, especially those relating to fault movements, should be found. Fig. 15 is a view of the foundation of the Kensico Dam. It is a narrow V-shaped gorge, at contact of Fordham gneiss (left) and Inwood limestone (right). The excavation is more than 100 ft. below the ground surface.

Explorations showed that the limestone, which was exposed in the bottom of the valley (Fig. 15), is 400 ft. thick and that, as a whole, it was in no poorer condition than the other formations. Perhaps, it is in better condition than the schist, because the latter is so much more broken.

The chief problems to be settled by detailed exploratory work were:

First.—The amount of drift cover and its character, especially its water-bearing quality as affecting construction.

Second.—The extent and distribution of weak zones or any broken condition of the rock.

Third.—The extent of weathering disintegration and decay.

Fourth.—The perviousness of the rock itself.

All these questions were determined within reasonable limits and were consistent with the earlier general estimate of conditions. After all the exploratory borings had been made and the facts bearing on these points had been summarized, it became evident that the more northerly lines had the soundest rock. The dam was placed, therefore, some distance north of the site of the existing old dam. On account of the discovery of considerable rock decay, especially at the junction between the gneiss and the limestone, and the presence of considerable jointing in the rock itself, particularly in the Manhattan schist, a design was adopted that provided for stripping and considerable excavation of the surface rock and a deep cut-off trench.

Of almost equal importance to the question of location and the quality of foundation is the problem of materials for construction. The dam required approximately 1 000 000 cu. yd. of structural material and the decision to use stone facing, if a suitable quality could be found near enough to be utilized economically, emphasized the problem of local supply. The basal gneiss series on the east side of the reservoir carries a large quantity of igneous intrusive rock of essentially granitic composition. This rock, the Yonkers gneiss, is of strikingly granular habit in most exposures and disintegrates to a sand under certain kinds of exposure. However, blocks of this stone used in the oldest buildings of the region are well preserved, and the stone shows high strength and a satisfactory resistance to the ordinary disintegration tests. Even the somewhat weathered material, considered by no means in its best condition, shows surprisingly good results under the tests. The color of the stone and its structural markings are considered to be very attractive. No other masonry structure on the Catskill work has been more successful from the standpoint of the material used.

The East View Concrete Disintegration.—From Kensico Reservoir, the aqueduct turns toward the city with cut-and-cover and short pressure and tunnel sections with comparatively little incident beyond the occasional uncertainties regarding the quality of the rock or the encountering of exceptional decay and disintegration. In Elmsford Tunnel north, a long stretch of excessive decay introduced the usual difficulties in construction. The only unusual feature, however, sufficiently different from those encountered in many other places, to warrant special attention, was in the East View Tunnel, about midway between East View and Kensico Reservoir. After this tunnel was completed and had stood for some time, it was discovered that, along a considerable stretch of roof and side-wall, the concrete lining was badly disintegrated. Patches were discovered that had softened completely and, in a few places, parts fell from the roof. It was found, however, that the trouble was not general, suggesting that there was some particular cause connected with the ground itself, rather than any fault of construction.

The aggregate used in the concrete in this tunnel included a great deal of limestone. At the time of construction, the suitability of limestone aggregate was not questioned, because this tunnel was put under comparatively little pressure and there was no thought of particular difficulty from the surrounding conditions. On investigation of the condition of the concrete, it was found that many of these limestone fragments had been completely de-

FIG. 14.—VIEW OF STEEL PIPE SIPHON ACROSS SPROUT BROOK VALLEY.

FIG. 15.—VIEW OF FOUNDATION OF KENSICO DAM.

stroyed. The experiments in this tunnel further emphasized the unsuitability of limestone for concrete aggregate under miscellaneous or uncertain conditions, especially if there is any probability of acid waters coming in contact with the concrete.

An investigation showed that the waters trickling into the tunnel in the part affected were charged with sulphates and had a destructive chemical action. Examination of rock that had been thrown out from the tunnel and from the borings made in this part of the ground showed large quantities of iron sulphide as a constituent. Blocks that had been exposed at the surface since construction were badly oxidized and showed abundant development of sulphate of iron which had been accompanied by the production of free sulphuric acid. A spoil bank of this kind of material had been thrown out on the surface almost directly over the most seriously affected part of the tunnel. From these facts it was concluded that the real cause of the trouble lay in the oxidization of the sulphide content of the rock, and the opening of an underground escape for the downward circulating water which, therefore, could leach these soluble matters out of the rock dump and reach the tunnel immediately below with the result of continuous destructive attack on the tunnel lining. Study of the methods of overcoming the trouble emphasized the difficulty of removing the cause. It was finally decided to reinforce the weakened part by lining it with different material. Accordingly, a brick lining was put in and all voids were filled with cement grout for a distance of about 2 000 ft.

The City Tunnel

The aqueduct reaches Hill View just outside the northern boundary of New York City at Elevation 295. At this point, an equalizing reservoir with a capacity of 900 000 000 gal. is located, which distributes directly to the city. After exhaustive study of alternative methods a deep pressure tunnel was adopted to extend from Hill View southward through the city to Brooklyn, N. Y. This was to become the trunk line from which water could be taken at many points. As finally worked out, the water was also carried to Staten Island and the Borough of Queens by means of steel pipe extensions. The adoption of a tunnel plan emphasized the matter of natural ground conditions and made it imperative to conduct extensive investigations. The manner in which these were co-ordinated with the other engineering studies forms an instructive illustration of the manner in which the Catskill Aqueduct project was handled.

A thorough preliminary engineering and geological study was made before any steps toward exploration were taken. Taking into account chiefly the engineering works already in place in New York City and the known difficulties due to city development, three trial lines were laid out by the engineers between the starting point and objective in Brooklyn. At this stage, the geologists were asked to make a study of the surface conditions along these three lines and the adjacent ground to a considerable distance on each side. It was then necessary to decide whether a shift of any one of the lines would materially improve these conditions. After careful study it was found that a

reasonably clear choice of a line could be made, but that certain unfavorable features could be avoided by shifting it somewhat from its original course. The choice was based on ground conditions, without sufficient knowledge of other factors to be certain that this new course would be practicable from an engineering standpoint. Therefore, it went for the second time to the Engineering Staff for consideration, with the result that minor modifications were suggested for re-study. These modifications were found to be generally consistent with the geological conditions, and, thus, with very little additional modification, the course that the aqueduct should take through the city was tentatively established.

These preliminary studies were sufficiently detailed to determine the points of uncertainty that would require active exploration, the nature of these uncertainties of condition, the purpose of these additional investigations, and something of the amount of exploratory work required. All the exploratory work was done by borings, but no conditions were discovered after the course was fixed that required material shift of the line.

General Questions.—In conducting these studies, the following general questions were kept actively in the foreground:

1.—What is the character of the rock along the projected conduit at the proposed depth?

2.—Is the depth proposed an appropriate one for a pressure tunnel of this character?

3.—Does the character of the rock vary sufficiently to affect the cost or the safety of the tunnel, and would anything be gained in either respect by a change of position or change of depth?

4.—What principles are most fundamental in weighing the evidence and in judging these points?

5.—What are the most questionable points along the proposed tunnel and where is exploratory work necessary to determine the local conditions fully enough to satisfy the needs of this project?

6.—What borings or other field investigations should be made to determine the facts about the uncertainties along the line and to make certain of the practicability of the pressure tunnel?

Geological Formations of New York City.—The variety of rock types within the city limits is somewhat greater than along the remainder of the aqueduct, but a knowledge of the three standard formations is sufficient to an understanding of the nature of all the local problems. Originally, these three formations lay one above the other to a very great thickness, but they are now folded together so closely that the parts exposed after long erosion stand almost on edge. On this account, the formations appear at the surface as long strips with a general northeast trend. The bottom and the top formations are more resistant to erosion and weathering than the one between them. As a result, the major topography of Manhattan and all the regions lying to the north of the East River and Long Island Sound have developed a parallel ridge topography consistent with this structure. Narrow valleys or the depressions lying parallel to this structural trend are underlain in most cases by the

softer rock (limestone) and the ridges are either one or the other of the two resistant members. These formations are: (1) the Manhattan schist at the top of the series; (2) Inwood limestone, the intermediate member; and (3) the Fordham gneiss, the basal member.

Originally, these formations were sediments varying from sandstones and limestones to simple mud shales. Now, after long metamorphism, these are gneisses, marbles, dolomites, and schists, each type presenting many variations in minor character and quality. The Manhattan schist, the youngest member, is essentially a mica schist. It is usually comparatively coarse and flaky in structure and inclined to be crumpled and somewhat bunchy. It is impregnated with igneous material which gives the rock a bunchy appearance or introduces stringers or dikes of pegmatite. Rock of this formation, because it is made up of very durable minerals and has a structural habit that makes it work in a massive form with reasonable satisfaction, has been considered suitable for tunneling.

The Inwood limestone is a coarsely crystalline dolomitic limestone. At depth, the rock is sound, but at the surface it crumbles readily under weathering influence and is comparatively easily eroded. Therefore, these belts of limestone are the lines of depression in the local topography. On the general principle that limestones of all grades are less stable where solution is possible than rocks made up of crystalline silicates, it was considered that long stretches of the Inwood limestone should be avoided if possible.

The Fordham gneiss is a black and white banded rock, made up chiefly of schistose and granitic bands. In some places much granite occurs in this formation, such as the "Yonkers gneiss". On the Brooklyn side, another similar occurrence is known as the "Ravenswood granodiorite". It is composed of durable material, but on account of its strongly banded structural habit, it tends to break into slabs, thus introducing a behavior somewhat more troublesome than that of the Manhattan schist.

Principles of Judgment.—At least one other structural feature must be considered. This is the crush zone or fault zone along which movement has taken place and along which rock is broken or weakened enough to encourage deeper decay and alteration than at other places. On the surface, these weakness lines are indicated by depressions. Relying on such knowledge of the importance of these conditions as was appreciated at the inception of this enterprise, the following principles were accepted as suitable guides, both in the matter of choice of location and exploration:

First.—It is in general desirable to avoid location in or near to a contact between two formations, as this is likely to be a zone of weakness underground.

Second.—Nearly all fault lines and crush zones are also lines of special weakness, and on this account it is desirable to avoid them in the manner indicated in Principle 1.

Third.—The behavior of the Inwood limestone is more uncertain than any of the other formations and, therefore, should be avoided as much as possible.

Fourth.—The simple igneous units such as the Yonkers gneissoid granite and the Ravenswood granodiorite are probably more uniform and consistent in their behavior under tunneling than any other formations, because of their simple crystalline character. For somewhat similar reasons the Fordham gneiss and the Manhattan schist may be considered comparatively satisfactory formations, although neither of them is as uniform in structure as the other two.

Fifth.—Along the lines of contact between the several rock formations and along crush zones, superficial decay and disintegration are much deeper than at other places. These places are practically the only points at which construction difficulties are likely to be encountered. They are also the chief points where the inflow of water and falling rock may be expected to be greater than usual.

Sixth.—The deepest erosion, marking pre-glacial stream channels, is to be expected also along the lines of contact and along the crush zones. The depths that these stream channels may reach cannot be determined without exploration. The positions of the most important spots, however, are indicated with reasonable accuracy so that exploratory work can be confined to definite places.

Seventh.—The overlying glacial drift is variable, but, for the most part, is very porous and water-bearing, especially where heavy cover is to be expected. This condition is a factor of importance in considering methods of construction.

Tunnel Location.—Basing judgment of the advantages and disadvantages of the trial lines on the principles just stated, it seemed reasonably clear that one of the three original alternative lines had decided advantages over the others in the proportion of better grade of rock and avoidance of questionable zones. One of the lines had an unnecessarily long stretch in the limestone formation. A second had a considerable length across a part of New York City where the underground formations are wholly obscured by drift. On the whole, the advantage seemed to lie with the trial line that was located farthest to the west, running from Hill View southward past Jerome Park Reservoir, crossing the Harlem River and running almost the entire length of Manhattan Island before crossing to Brooklyn.

In this connection, all the exploratory data available in the city were re-studied and a new geologic map was made of that part of the city within reach of the project. This map showed considerable differences from the standard geologic map of Folio 83 of the U. S. Geological Survey, some of the points being regarded as very radical changes. As a guide to location studies the contact lines between the several rock formations were re-drawn as accurately as possible, and special attention was given to lines of structural weakness and to depressions in the rock floor marking pre-glacial drainage. The course of the City Tunnel was based on these studies. Although this general location was made before additional exploratory work was undertaken, no new conditions were discovered of sufficient importance to require material modification. The question of depth, however, was not settled until the exploratory data from the borings were available.

Questionable Points.—By detailed studies of the ground along the course adopted for the City Tunnel, it became certain that, for the greater part of the distance of nearly 18 miles, the geological conditions were so fully determined and so satisfactory that no exploratory work would be necessary. Ordinary geological interpretation also reasonably established that long stretches of ground, even where direct observations of the bed-rock were not frequent, would not present conditions of sufficient uncertainty to warrant extensive investigation. At four points, however, it was realized that not only were the actual conditions unknown, but the evidence indicated greater probability of weakness than at other places. It was also expected that in places the rock floor would be deeply eroded and show structural weaknesses. These spots would probably control the depth of the tunnel and determine the difficulties of construction. It was advised, therefore, that these points should be thoroughly explored. These four places were:

1.—The vicinity of the Mosholu Parkway;
2.—The Harlem River crossing;
3.—The 125th Street cross-town depression and its extension southward to Central Park; and
4.—The lower East Side from the Bowery across the East River to Brooklyn.

Certain surface conditions suggested the probability of a cross-zone of weakness at Mosholu Parkway. This was not expected to be of as much importance as the others, because of the very substantial Yonkers gneiss type of rock. Explorations, however, showed satisfactory conditions at this point at the depth adopted.

At the Harlem River, the tunnel would cross from Fordham gneiss through the Inwood limestone to the Manhattan schist. This was known to be a line of depression and weakness, and although the geologic structure in general was well established, the exact conditions had to be determined on the basis of which the depth of the tunnel could be fixed. Explorations were conducted, therefore, in sufficient detail to determine the exact boundaries of the formations and their condition, particularly at the contacts.

The 125th Street cross-town depression is a prominent feature, and it was appreciated in the beginning that it indicated a structural weakness such as a crush or fault-line zone. Explorations at this point extended from 125th Street southward and showed the correctness of this interpretation. The earliest borings indicated not only that crush zone conditions existed, but that the rock floor was eroded to Elevation — 190. The 125th Street depression is one of the deepest erosion lines within the limits of the city, and is much more pronounced than the course of the East River. Exploratory work, carried southward in the vicinity of Morningside Park, as far as 110th Street, indicated a somewhat less prominent weakness extending parallel to the contact of the formations with comparatively deep erosion also along that line. It was partly to avoid the worst conditions of this zone that the tunnel was turned eastward at 106th Street instead of 110th Street. Explorations enabled an accurate map of the boundaries of the formations to be made and

the major structural features were determined. It was these findings that determined the course of the aqueduct and its depth.

The lower East Side of the East River Section also required extensive study, partly because of the greater extent of unknown or questionable ground, the entire lack of outcrops, and the dearth of earlier exploratory data. Nearly all the distance between the Bowery and the Brooklyn side of the East River required detailed exploration. It had always been assumed that the East River follows a zone of considerable weakness or a change of formations. The revised map threw considerable doubt on this assumption and the explorations proved also that the bed-rock condition of the East River south of 30th Street to Brooklyn Bridge is comparatively simple and sound. A little farther to the west, however, between Forsythe and Clinton Streets, lies a belt of ground in which great complexity of structure and very deep decay were discovered.

This decay and disintegration were found to extend extraordinarily deep. The rock floor reaches Elevation — 200 and is below Elevation — 100 for nearly the whole distance. In this section of the rock floor, the deepest part is more than 100 ft. deeper than at the East River itself. Doubtless, the pre-glacial drainage was through this territory across the lower East Side instead of along the present course of the East River. The present course is evidently controlled by the accumulations of obstructing glacial drift which filled the old channel more deeply than some of the adjacent ground, so that when post-glacial drainage was finally established, the new watercourses differed from the original ones.

Additional exploratory work was done at certain other points along the projected line as a check on interpretations and as a basis for contract specifications. Three of the four sections originally chosen for detailed investigation proved to be the critical and controlling ones in determining the nature of the most questionable conditions to be encountered and in deciding on the depth of the tunnel. No others were discovered, even during construction, of so great significance.

Depth of Tunnel.—The comparatively sound conditions of the whole northerly portion of the line to the Harlem River made it possible to construct the tunnel at a moderate depth, about Elevation — 150, to that point. The controlling feature of the next section, however, was the Harlem River, and as it showed a weakened condition of the rock to Elevation 160, it was decided to place the tunnel through this portion at a depth of about 350 ft. below tide level. Fig. 16 is a geological profile of the Harlem River Tunnel of the Catskill Aqueduct, showing the rock penetrated.

At the 125th Street depression, pre-glacial erosion extends to a depth of 200 ft. and the rock is somewhat broken. It became necessary, therefore, to place the tunnel still deeper. It was finally located at about Elevation — 350. As the quality of rock improved, and the floor was much shallower for many miles south, the design adopted allowed the tunnel to rise on an incline to Elevation — 250, and this level was maintained as far south as the vicinity of the complex conditions of the lower East Side, and the East River. The ground of the lower East Side, which showed pre-glacial erosion deeper than

Elevation — 200 and a weakened rock condition and decay to Elevation — 600, was regarded as so questionable in its behavior both for construction and permanence that it was determined to depress this section to Elevation — 700 in order to reach firm rock. On the Brooklyn side of the East River, the tunnel grade was raised again to Elevation — 250 to the terminal.

Fig. 17 shows the rock 700 ft. beneath Delancey Street. This rock is Inwood limestone, with complicated folding, crumpling, and faulting, and is cut through by a granite dike. The folding is characterized by remarkable crumpling varying from small plications of a few inches to great arches such as form the major ridges of the island and indicating a former deformation of the rock of considerable magnitude. Much trouble may be experienced in tunnels through folded rocks if they show marked fracturing, and careful attention must be given in such cases to the geological structure.

Observations on the results of construction and operation indicate that the deeper positions are the most successful. Athough Elevation — 700 would doubtless be excessive for the whole tunnel, the success of the work at the East River, together with difficulties that arose in certain of the shallower sections, have led to the conviction that the tunnel is nowhere placed too deep. There are weaknesses in all types of rock, and it is not the average condition but the weak spots which control the efficiency of the conduit under operating conditions. The behavior of the rock formations under construction and operating conditions has shown that the limestone formation at the depth of the tunnel has been a satisfactory type of rock, much more so than was expected. The difficulties expected from it were perhaps overstated, because of its behavior at the surface. There is no reason to believe that those parts of the tunnel where limestone forms the walls will be much less successful and permanent than other parts.

At some places, the banded Fordham gneiss formation has proved to be unsatisfactory as a rock for tunneling, because of its tendency to break out in slabs more extensively than either the limestone or the schist. The schist which in ordinary exposure is strongly foliated, has proved to be a satisfactory formation. Its crumpled nature and the fact that the schistose structure stands at high angles in the ground, coupled with the additional fact that the tunnel is at sufficient depth to avoid superficial weaknesses, has furnished almost ideal rock conditions. This rock could be broken very true to the required lines, and it seldom presented structural difficulties or dangerous ground.

Considerable difficulty was experienced in driving through those rocks that exhibited a strong tendency to break into thin slabs, especially when this condition was developed in rock that lay nearly flat or crossed the tunnel at a very slight angle. The Fordham gneiss presented these conditions and, occasionally, the other formations. Where crush zones were encountered not only was the ground dangerous for working because of the tendency of blocks to drop from the roof, but in some places the inflow of water and the disintegration of the rock on exposure gave additional construction difficulties. At 106th Street, where the tunnel crossed a known fault line with a wide crush zone, the rock did not present any unusual features when the

FIG. 17.—ROCK FORMATION 700 FT. BELOW DELANCEY STREET, NEW YORK CITY.

tunnel first penetrated it, except that it broke out in small pieces. Later, after exposure, the walls of the tunnel showed extensive disintegration and softening. At 106th Street, a heavy steel shell was placed for 110 ft. through the crush zone.

A worse condition, as far as excavation was concerned, was in the crush zones beneath the 125th Street depression, and somewhat similar conditions were encountered in the vicinity of 146th Street. At these places, the rock was broken more in blocks than at 106th Street and these blocks would drop out. In the vicinity of Jerome Park and elsewhere, some of the joints in the rock were water-bearing, one of which furnished for a time as much as 500 gal. per min. It was thought at first that this might connect with the reservoir, but the later behavior seemed to indicate that the chief water supply was local and connected only with the open joint system of the rock and the overlying soil.

At many points along the course of the tunnel, joint systems of considerable prominence were encountered. As a rule, these joints were not heavily water-bearing, but it was recognized that water would be lost through them, unless they could be closed. When the hydrostatic test was made, leakage developed near Madison Square, New York City. This section was repaired by lining the tunnel for some distance with sheet copper and by grouting the rock joints. No other sections of the tunnel have thus far developed weaknesses of this kind and its operation is considered to be successful.

Staten Island Development

Water from the Catskills is carried to Staten Island in steel pipes from Shaft 24. A cast-iron pipe was laid through the silt of New York Bay at The Narrows. A short tunnel in serpentine rock conducts the water to Silver Lake Reservoir on the high ground of Staten Island. The bed-rock is serpentine, much fractured at the surface, and of complex internal structure, but essentially substantial and water-tight at a moderate depth. The exposed parts are considerably broken and allow the circulation of water through the network of fractures or joints. This rock, however, is covered with drift, of which part is heavy substantial till and part assorted gravel and sand.

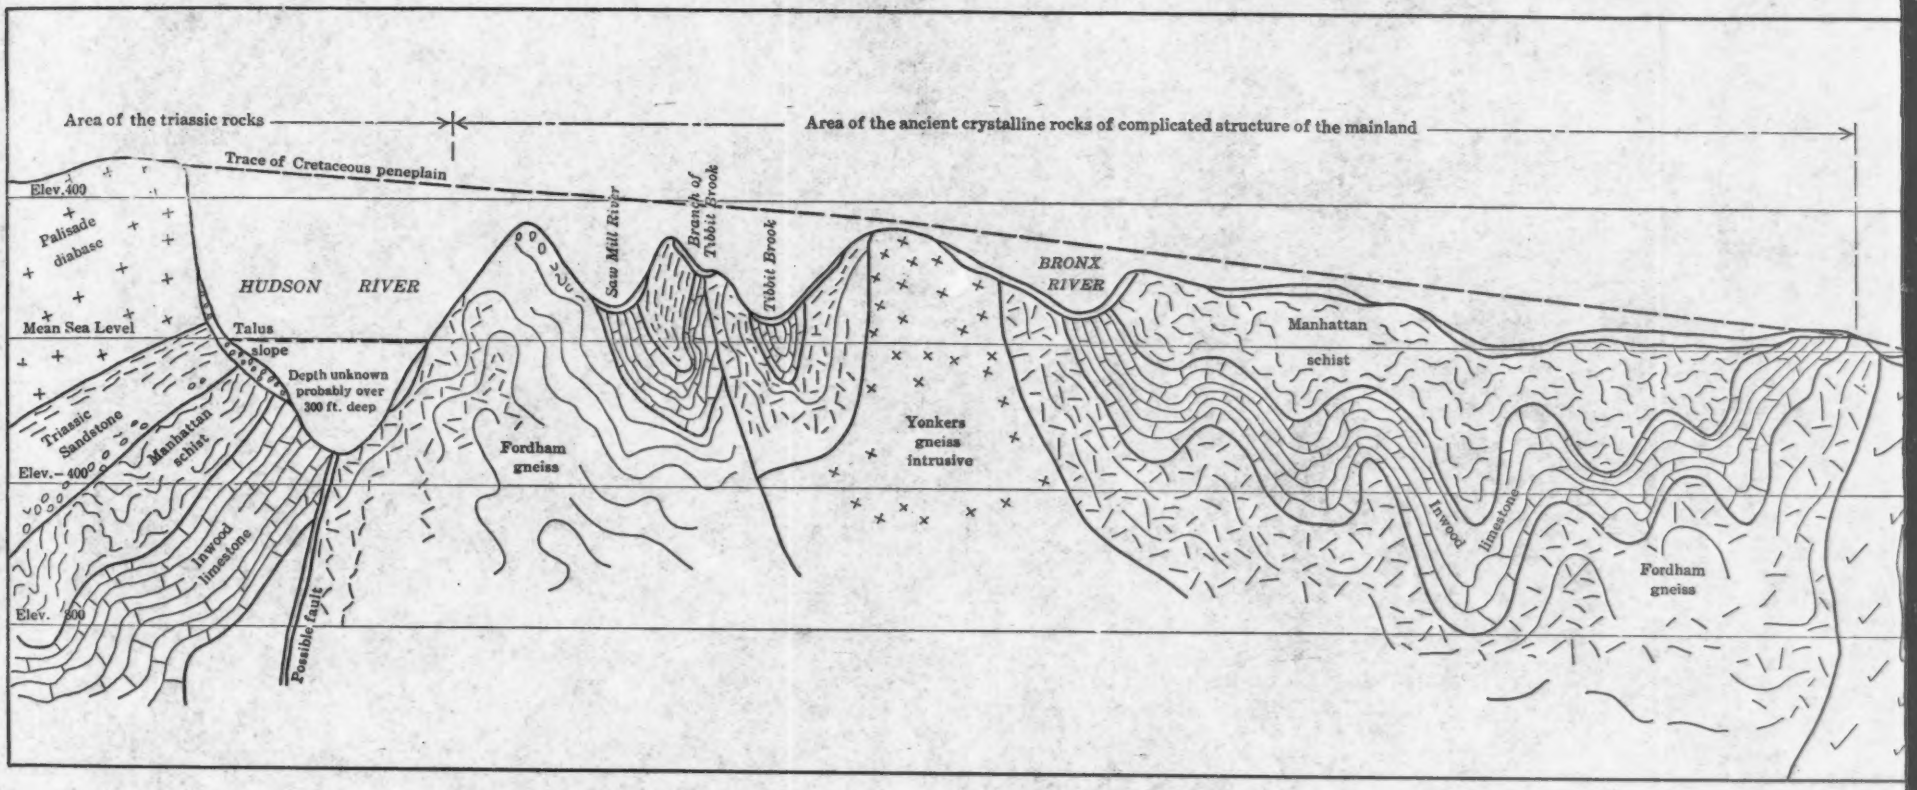
The site chosen for the reservoir is that of an original natural lake. It is, however, surrounded by glacial deposits, and explorations showed that these deposits, both at the southerly outlet and at the westerly side, are comparatively deep and variable in quality. The borings, however, indicated such a succession of interfingering or interlocking of porous and of impervious portions, that it was thought practicable to depend on this ground to hold water. The dike at the westerly outlet was constructed with a core-wall that reached to bed-rock, but did not extend the entire distance across the depression. The southerly outlet was so deep that no attempt was made to put a core-wall to bed-rock.

Some leakage developed under operating conditions; both to the west and to the south, the water travels in a roundabout way through the interlocking irregularly distributed porous parts of the drift, evading the more

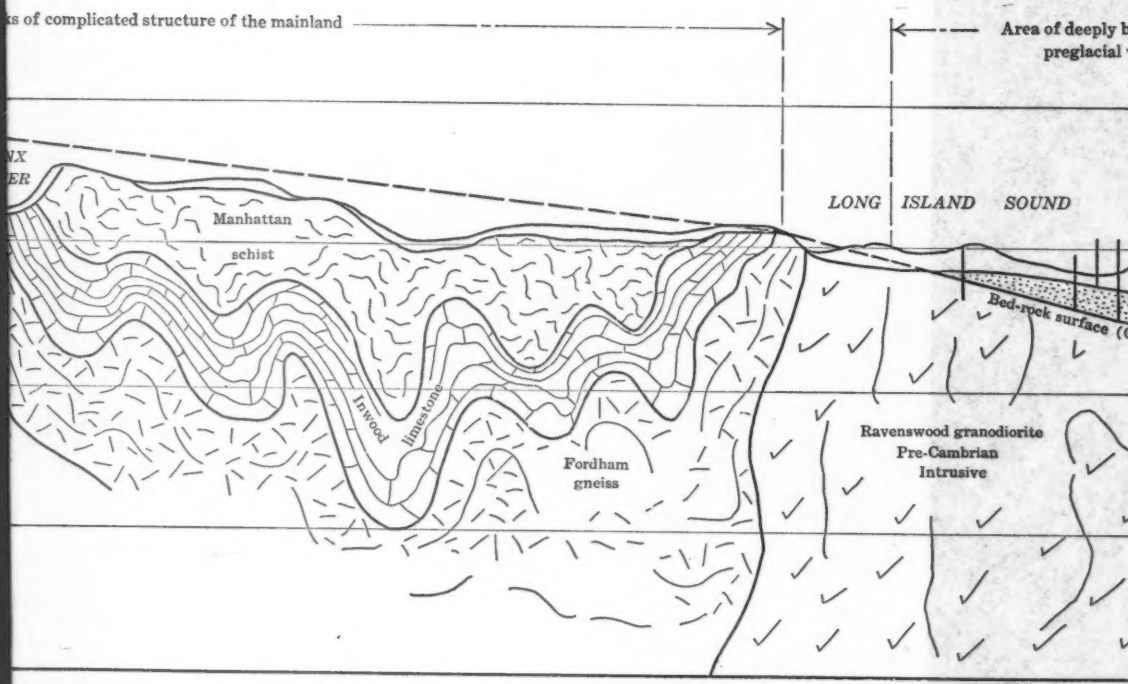
substantial obstructing dikes and impervious material. Undoubtedly, greater reliance was placed on the quality of the drift and the water-tightness of the floor than conditions warranted.

Long Island

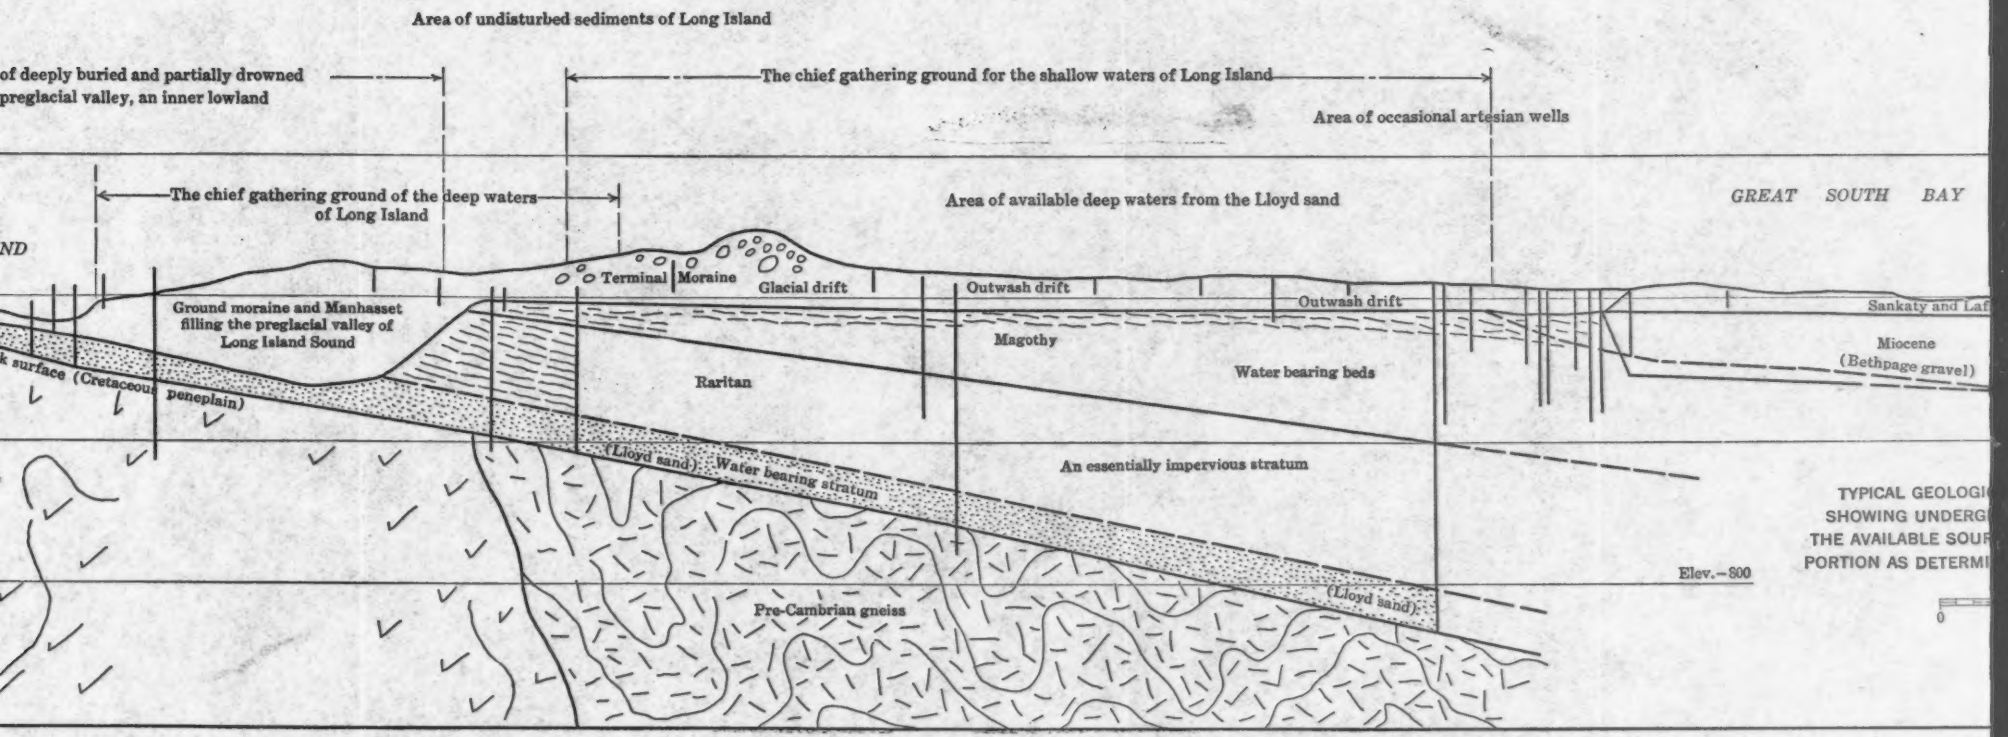
Originally, the development undertaken by the Board of Water Supply included a project for the development of additional supplies from Long Island sources. For many years the City of Brooklyn had secured part of its water from surface streams and wells many miles beyond the city limits. It was intended to develop the underground supply of Suffolk County and considerable progress was made before restrictive legislation caused the temporary abandonment of the Long Island project.



Underground supplies alone were sought, which, it was expected, might be increased by obstructing the run-off from some of the small streams in such a way as to give greater opportunity for the water to soak into the soil. The essentials of this project, therefore, have to do with the quantity and behavior of recovery of ordinary well waters and the underground conditions which govern them.



The coastal plain formation shown on Plate III, together with the glacial deposits on Long Island, overlie the ancient rocks and contain the porous members which are the main sources of water supply.



Immediately beneath the glacial drift of Long Island is a series of sedimentary sands and marls and clay dipping gently toward and beneath the sea. This whole series, in turn, lies on a uniform base of crystalline rock, the old eroded surface of which slopes in the same direction. None of the overlying strata extends farther inland than Long Island Sound and only the lowermost reach that far, because later erosion has beveled across these beds, so that if the glacial drift were scraped off, one could walk across the exposed layers one after another from Long Island Sound to the ocean. Thus, all of them are open to the entrance of percolating water along their entire landward extension.

All the layers are heavily covered, however, with glacial drift, including mixed morainic materials and an immense quantity of assorted gravel and sand. This glacial drift practically covers everything on Long Island, and its extreme porosity, which is its most striking characteristic, is also a most important factor in the problem of water supply, as ordinary rain water soaks into and through this drift cover and enters the underlying beds in great quantities. All these materials, both the glacial drift and the underlying sedimentary beds, are water-bearing, but because of their irregular surface and porosity, the depth to permanent water differs considerably.

Water obtained from these underground sources comes both from the drift and from the sedimentary beds at many different levels. Most of the supplies used are shallow and belong chiefly to the glacial drift. Deeper wells penetrate successive water-bearing sedimentary beds, some of which furnish a high grade and abundant supply. A particularly prominent source of high-grade water is known as the "Lloyd sand", which is one of the deepest layers,

and wells penetrating this stratum sometimes give Artesian flow. Many of the strata are too closely textured to permit ready movement of water. All the waters are of surface or rain-water origin. None of them comes from distant sources and the supply is limited to the quantity of such percolation. On both the north and south margins of the island, salt water encroaches on the fresh-water supply, the encroachment depending on the quantity of withdrawal.

The method of development, therefore, involves the sinking of wells into these water-bearing materials and developing this important supply. A large project would necessarily remove considerable of the underground water and would lower the ground-water level at the points of extraction. This feature was emphasized by the objectors to the plan, who finally caused temporary abandonment of the project. The ground-waters of Long Island are high grade and a large supply could easily be made available. It is near New York City, and development would cause a minimum of disturbance to other kinds of ownership and interest. Ultimately, as the city's demands grow, this source will be used on a much larger scale. It is the only near-by source of any consequence and also the only one capable of so large a development at small expense. The conditions governing this supply and the methods of recovery and control are certain to receive a great deal of attention in the near future.

Acknowledgments

The development of the Catskill Water Supply was begun in 1905 and was conducted by the Board of Water Supply, New York City. The Engineering Staff was under the direction of J. Waldo Smith, M. Am. Soc. C. E., Chief Engineer, until July, 1922; Thaddeus Merriman, M. Am. Soc. C. E., formerly Deputy Chief Engineer, is now Chief Engineer; John R. Freeman, Past-President, Am. Soc. C. E., William H. Burr, M. Am. Soc. C. E., and the late Frederic P. Stearns and Alfred Noble, Past-Presidents, Am. Soc. C. E., were the Consulting Engineers. Mr. J. Waldo Smith is now also Consulting Engineer. Professors W. O. Crosby and J. F. Kemp and Dr. Berkey were the Consulting Geologists. Acknowledgments are made by the writers to all who have contributed to this work.

DISCUSSION

ALFRED D. FLINN,* M. AM. SOC. C. E. (by letter).—The geographical extent of the Catskill Water System and its vital importance to a great community, added to the diverse geological features of the region, make this paper one of unusual interest. In passing, the writer would express his conviction, based on thirteen years' connection with the work described, and as many more years with other large projects, that the municipal authorities of the City of New York were fortunate in their geological advisers and in the fact that Chief Engineer J. Waldo Smith, Mr. Sanborn, and other engineers on the staff possessed knowledge and appreciation of geology. The paper is so complete in its description and so instructive in its correlation of engineering location, design, and construction, with geological exploration and interpretation, that the writer will simply emphasize a few general considerations.

That geological aid pays in constructional as well as in mining operations is believed to have been demonstrated. For greatest results in economy and security, it is essential that:

1.—The engineer and geologist should co-operate from the beginning of the preliminaries of the project.

2.—The geologist should be well informed on the broad geology of the region, the detailed structural geology of the location, the mineralogy of the rocks and the overburden of earth, and the present and ancient water circulation, or drainage.

3.—The geologist should have some comprehension of the nature and requirements of the structures and excavations making up the works of the project.

4.—The engineer should have some knowledge of geology and mineralogy.

5.—Even routine field explorations (soundings, test-pits, borings) should not be delegated to an assistant lacking understanding of the importance of each feature of such explorations. Every step requires the intimate supervision of an engineer possessed of knowledge of geology and keen appreciation of the importance of carefulness, close observation, and complete records, with clear, full headings and dates.

6.—The owner (or other person having control of the general policies) must have foresight and courage to spend enough money to obtain adequate information and make a thorough study of the facts gained.

7.—Full use should be made of the geological information and deductions in the design, location, and method of construction.

8.—All geological information, with suitable explanations and safeguards, should be made accessible to intending bidders, who should be required to examine such information while preparing their bids. Exhibits for bidders should include not only maps, sections, and statements, but also test-pits and materials removed from them, cores, and other samples from borings

* Secy., United Eng. Soc., and Director, Eng. Foundation, New York City.

(all of them, or as many as practicable), and every other physical object of contributory value, supplemented, if advantageous, with photographs.

9.—The geological information should also be accessible to the engineers and contractors during construction.

All these statements are somewhat obvious, but the results achieved on the Catskill Aqueduct work show many advantages which may be realized by the proper utilization of the skill of the geologist as an adjunct to good engineering.

GEORGE G. HONNESS,* M. AM. SOC. C. E. (by letter).—This paper is particularly interesting to those who were associated with the authors in conducting the work by which the geological information was secured. It also should be of value and interest to the Engineering Profession in general.

The part of the paper covering the work from the Ashokan Reservoir to the Atlantic Ocean is so complete, being based not only on the knowledge gained by borings, but also by the actual construction, that little can be added. The work on the Schoharie development is not so fully covered, as the authors did not have personal knowledge of the later investigations and the progress of construction. The writer, therefore, will try to add something gained by knowledge of the actual construction work.

Schoharie Reservoir and Gilboa Dam.—The sub-surface investigations for a site at which to construct a dam to form the Schoharie Reservoir extended from Pratt Rocks to Gilboa and located the pre-glacial gorge for a distance of six miles; everywhere the gorge below the floor of the old valley was filled with material which may be considered as generally impervious. The course of the old gorge was sinuous; near Devasego Falls, and, again, at the site of the Gilboa Dam, it makes a complete letter "S"; in the vicinity of Manorkill Falls, there was apparently an abrupt drop in the floor of the gorge and probably a "fall" existed in the pre-glacial stream. At Gilboa, the bottom of the pre-glacial gorge is at least 130 ft. lower than the post-glacial. The lowest part of the gorge is westerly from the limits of any engineering structure and is covered to a great depth by a very impervious clay. An investigation was conducted to determine the possibility of a filling of pervious character of wide extent in the bottom of the valley up stream from the dam. After making a number of special borings, it was concluded that if exposed rock adjacent to the dam was covered by earthy material deposited through water, no appreciable loss of water need be anticipated. Subsequently, in excavating the core-wall trench, it was concluded that the excavation was passing close to the south side of one of the steps of the pre-glacial gorge, and that some of the talus pushed off the sides of the old gorge by advancing ice had been penetrated. For a part of the distance, the core-wall extends to rock, and from where it leaves the rock to the known limits of this pervious material, an effort will be made to consolidate it by grouting.

The authors enumerate the "Geologic Conditions Affecting Dams", and it may be of interest to outline the methods used to determine the extent of the excavation for, and the treatment of, the foundation of the Gilboa Dam. The

* Dept. Engr., Board of Water Supply, New York City, Grand Gorge, N. Y.

borings made for the preliminary investigation of the dam site, and also those made later for use in planning the structures, are shown on Fig. 5; many of these borings were deepened, those on the hillside being carried down to the level of the floor of the valley and those in the bed of the present stream to a depth of 100 ft.

Pressure tests were conducted to locate seams in the rock, and to determine their extent and their approximate water-carrying capacity when subjected to a pressure equal to that which would result from a height of 10 ft. of water over the crest of the dam. An apparatus similar to that used on other investigations made it possible to segregate each vertical foot of the diamond drill hole, to subject it to a pressure, and to make a volumetric determination of the quantity of water pumped. These tests showed that, in general, considerable leakage occurred in the upper part of the holes near the surface of the rock, both through vertical and horizontal seams; the number of seams and quantity of leakage decreased as the depth increased. When a test of one hole was in progress, observations were made in adjacent holes to determine the extent of leakage planes. No extensive leakage planes were detected; in some cases, however, responses were obtained in holes 400 ft. away. Seams were located both in the shales and in the sandstones, but they were more clearly defined in the sandstones.

In order to analyze and visualize the results of the test, a model was constructed, the outline of the dam and spillway being in plan. At the location of diamond drill holes, wooden circular rods were inserted and painted to indicate the various stratifications of rock. A blueprint showing the results of pressure tests was attached to the rods by thumb tacks at the proper position; cords leading from rod to rod showed the water circulation between holes and its direction. From a study of the results, a tentative depth for the general foundation of the dam and of the bottom of the cut-off excavation was fixed, and the depths to which to extend diamond drill borings for grouting were determined.

Fig. 18 shows a part of the profile which was issued to the field engineers as a guide to excavation. The line for excavation under Item No. 7 was tentative, because it indicated the extent of the excavation for the foundation of the dam, which was dependent on conditions disclosed as the work progressed. The line for excavation under Item No. 9 indicates the bottom of the cut-off trench, and is carried below the zone of seamy rock. Core borings inclined at an angle of $22\frac{1}{2}°$ with the vertical, were made for the purpose of intersecting heading joints and planes and thereby causing more effective circulation of the grout. The diamond drill holes were extended to a depth below which the pressure test showed only slight seams which carried off very little water.

The grouting is not done until masonry has been placed in the cut-off trench and to a substantial depth over the entire foundation of the dam. Steel pipes are caulked into the diamond drill holes and carried up with the masonry. Fig. 18 shows much of the information on which conclusions were based.

Perhaps the most interesting geological feature to the general public disclosed by the work in the vicinity of Gilboa was the finding of fossil trees of the Devonian period, said to be the oldest flora of the earth's history. The first fossils were discovered several years ago when a section of State highway was under construction. Dr. John M. Clarke, of the State Museum of the State Department of Education, asked that a lookout be kept for specimens as the work progressed. Before the construction had progressed far enough to disclose any fossils, representatives of his Department discovered some very good specimens at Manorkill Falls at about Elevation 1120. As the excavation for the dam progressed, other specimens were found at Elevation 1020 and at the quarry for facing stone at Elevation 960. In each instance, they were bedded on a thin layer of dark shale which represented what was left of a black muck swamp in which they originally grew. These fossils are said by the geologists to be 100 000 000 to 300 000 000 years old and are the only specimens yet found. A large collection has been placed in the State Museum at Albany, N. Y. Specimens are also in possession of the Harvard University Museum and the American Museum of Natural History in New York City.

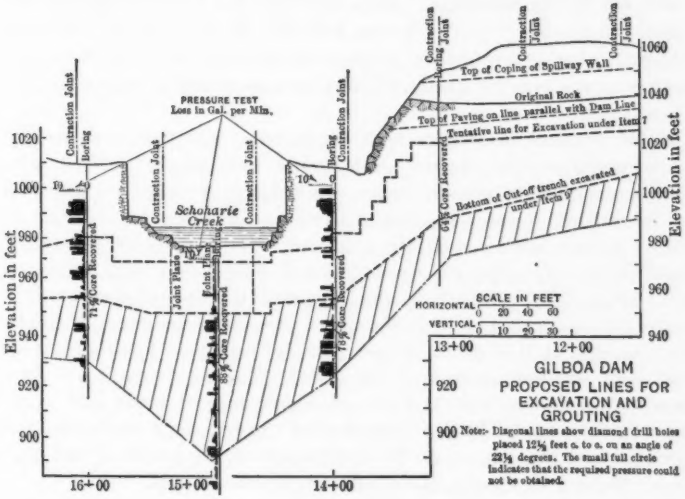

FIG. 18.

Shandaken Tunnel.—The preliminary investigation of sub-surface conditions disclosed that each small valley crossed by the line of the tunnel had its own particular gorge, and the investigation was sufficient to ascertain whether the pre-glacial gorges were deep enough to reach the grade of the tunnel, which occurred in only one case.

If the tunnel had been constructed on the hydraulic gradient at the Bearkill Gorge it would have penetrated the filling of the gorge, a disconcerting occurrence in tunnel construction. To avoid the possibility of this, the tunnel

was depressed so that there would apparently be a rock roof 100 ft. thick at the Bearkill Gorge. The Shandaken Tunnel, therefore, acts as a pressure tunnel for about 3½ miles of its length.

It was the judgment of all who had studied the borings that comparatively little support would be required and that where it was necessary it would be temporary, merely to protect the workers from small fragments spalling off. The condition encountered required that about 50% of the tunnel should be supported by either temporary or permanent timbering. The exposure of the red shales and sandstone to the atmosphere caused masses of sufficient size to fall, and secure protection was necessary. In the gray sandstone, "popping rock" which was observed at Hudson River shafts and other parts of the aqueduct, occurred, particularly in the north tunnel from Shaft 5. This rock appeared to be of the best texture and sound, but it required permanent support. After the heading and the tunnel for a distance of 100 to 200 ft. from the face of the heading had been excavated, it was common to hear a loud report and then a large slab of rock would be observed to loosen. These occurrences caused a panicky feeling among the men, as frequently large pieces of rock fell shortly afterward. After the timbering had been erected and dry-packed, the "popping" was no longer noticed. With the strain removed, it is problematical whether further working of the rock would have taken place, but the chances were too great, and support was carried as close to the heading as practicable.

A few crushed zones have been encountered, but they have been passed without much trouble. In the south tunnel, from Shaft 3, a horizontal clay seam, surmounted by a badly broken up bedding of shales, was encountered, and the inflow of water reached a maximum of 170 gal. per min. As the heading was advanced and heavily timbered, several crushed zones were passed where the stratification was tipped up and very blocky and, finally, a mud seam, varying from 5 to 7 ft. thick, crossed the line of the tunnel. This was possibly a decayed rock or, perhaps, a pre-glacial residuary decayed material, although, at that depth, it seems hardly possible. For the next 100 ft., three badly crushed zones were penetrated. The rock was broken by cross-joints and shrinkage planes, many of which dripped water and were filled with a bluish clay. The disintegration of the red shaly sandstones and the filtering in of the clays give the appearance of a mixture of red and gray shales. Beyond that point, the conditions become normal.

In the north tunnel, from Shaft 4, about 3 600 ft. from the place just described, a crushed zone which gave much trouble, was penetrated.

In the north tunnel, from Shaft 5, a small crushed zone and slight faulting were found, and, at one place, a badly disintegrated rock. Gas in small quantities entered in a number of places, and Plutonic water having a solid content three times that of the water of the Atlantic Ocean and one-half that of the water of the Dead Sea has been found, that was undoubtedly entrapped and held in cavities at the time the rock was being formed.

At present, only 4 000 ft. of the 18.1-mile tunnel remains to be excavated, and it is unlikely that more serious troubles than those described will arise.

At the southerly end, a short stretch of tunnel in earth is to be excavated, that presents many of the difficulties of soft ground work. The adoption of careful soft ground methods by an expert on that kind of work gives assurance that it will be successfully completed.

The tunnel has been remarkably dry, the maximum quantity of water pumped at any one time from one shaft being about 170 gal. per min.

The authors state in a number of places that, generally, the strata in the Catskill region "dip to the west at a slight angle". It has been found that the dip is from 1° 30′ to 2° in a southerly direction, consequently, that part of Plate II, covering the Shandaken Tunnel, should be corrected to agree with the determination given.

The character of the rock and the superior equipment and organization of the contractor led to remarkable progress in excavation. With twelve headings being worked, more than one-half of which required timbering, a progress of 5 593 ft. per month was made. The average weekly progress (elapsed time, which includes time lost in re-organization) is 62 ft. of completed tunnel per point of attack, a much higher rate than that maintained on the tunnels of the Catskill Aqueduct. At the shaft, maintaining the best progress, the average was 90 ft. per week.

LAZARUS WHITE,* M. AM. SOC. C. E.—The speaker's knowledge of geology gained from Professor Kemp at Columbia University, was valuable, and was used for the first time on this work. It was a great help in anticipating underground conditions, which is essential in order to locate an aqueduct or dam in a country like that south of the Catskills. The superficial aspect of that country does not indicate the underground structure, which is the result of past geological conditions, and about which a competent geologist can tell a great deal. He cannot tell all about it, and that is where the danger lies. The engineer can co-operate with the geologist, but he must adhere to an independent judgment of the conditions based, not on a geological theory or accepted statements, but on borings. To do otherwise invites the risk of serious error. For instance, on the Rondout Siphon, with which the speaker is familiar, the geological predictions were good, but it would have been dangerous to have located the aqueduct on the basis of those predictions alone, because one of the gorges that the geologists had predicted would be deep, was shallow, and another that they had predicted would be shallow, was deep; if the depth of the tunnel had been determined in accordance with the predictions, a deep gorge would have been penetrated, which would have caused serious difficulties. However, these discrepancies were discovered by diamond drill borings long before the final profile was adopted. It does illustrate, however, that too great a duty should not be placed on the geologist. The location of the Loetschburg Tunnel was left to the geologists, and no borings were made. The result was that the tunnel penetrated a buried gorge, with disastrous results.

There were places on the Rondout Siphon at which a change of profile would have made a great difference in the amount of tunneling in Hudson

* Pres., Spencer, White & Prentis Inc., New York City.

River shale and Shawangunk grit. To determine the cost of tunneling in each of these rocks, two experimental tunnels, side by side, were driven 150 ft. in them. This work furnished valuable information, especially on the method of timbering the shale, and resulted in a large saving, later, in the cost of driving the main tunnel.

In the Rondout Siphon, a particularly bad condition was found in the limestones, and there was no method of locating the profile to avoid them. One of the geologists predicted very closely the caves that might be penetrated in driving that tunnel; however, those caves were below the gorges. The water circulated down and rose again under pressure, the conditions being similar to those which the same geologist had observed in Missouri.

In the speaker's opinion, this paper is a valuable one for engineers, and can be used to great advantage in schools to co-relate the study of geology with that of engineering.

WALTER E. SPEAR,* M. AM. SOC. C. E.—The authors are to be congratulated on their clear exposition of the many problems in engineering geology that arose in the construction of the Catskill Water-Works. Perhaps in no previous enterprise of the same magnitude has there been equal co-operation between the engineers and the geologists.

The Hudson River is the one large stream within the State of New York, that reaches the sea without crossing the boundaries of another State. It has been possible, therefore, with the consent of the State, to appropriate its waters for New York City, and no attempt has been made to acquire any source of supply outside the State. The one large tributary of the Hudson River in the vicinity of New York City—the Croton River—was developed as the first large source of supply. It was necessary, however, to obtain the next supply from a more remote tributary of the Hudson River, the Esopus Creek in the Catskill Mountains. The difficulties of conveying the Catskill Mountain supply to the city were those of constructing an aqueduct across the geological formations which, in this vicinity, have a general northeast-southwest trend. If the Housatonic River, which was suggested as a source of supply in 1900, or even the more remote Connecticut River, was in New York State, instead of in Connecticut, the transportation in a direction parallel with the strike of the geological formation would have been simpler than bringing the Catskill supply to New York City.

It can now be estimated that the probable date of exhaustion of the available water supplies for New York City is not very distant. Preliminary investigations, anticipating the acquisition of new sources of supply, have already been started, in which Dr. Berkey has had a part. Now, as before, no works outside the State of New York may be considered, and the problems confronting the engineers are the same as those of the Catskill works, namely, constructing reservoirs and building a large aqueduct that will pierce the mountains and cross the deep valleys lying between the city and any large source of supply that may be made available. A new conduit will probably be built in tunnel to a larger extent than the Catskill Aqueduct. However, the

* Dept. Engr., Board of Water Supply, New York City.

experience gained on the Catskill Aqueduct in tunneling, mostly through the same formations as will be encountered on a new aqueduct, gives assurance that, with the same care and thoroughness in making the preliminary investigations, no serious difficulty need be feared.

Something may be added to the statements made by the authors in regard to the investigations on Long Island, looking to the development of an emergency ground-water supply which could be made available in advance of the delivery of the Catskill supply. In 1907 and 1908, in addition to the mapping of the water-table in Suffolk County, the gauging of the streams, and the topographical surveys, the Board of Water Supply made a number of deep borings on the south shore of Long Island along the line of development of the proposed ground-water supply. One of these borings, having a 12-in. stove-pipe casing, extended to a depth of 900 ft.

These borings furnished much additional information on the geology of Long Island and led to the preparation of a plan for pumping a supply of 250 000 000 gal. of water per day from the "yellow gravels" of Southern Suffolk County. Professor W. O. Crosby, the Consulting Geologist on this work, made an exhaustive study of all the available data on the geology of Long Island, which, previous to the work of Messrs. Crosby, Veatch, Bowman, and others in 1903, was, as a whole, a comparatively unknown territory. In his report of 1910, which is as yet unpublished, Professor Crosby confirmed the conclusions, previously reached by the engineers, that, in Suffolk County, the only available water horizon from which to obtain a large supply was that in the "yellow gravels", which he classified as the Cohansey and Lafayette of the Pliocene, the Pensauken of the Epipliocene, and the glacial outwash of the Pleistocene, and which cover Southern Long Island to a depth of 50 to 200 ft.

He pointed out that the Bethpage gravel of the Miocene, an important horizon in Southwestern Long Island, represented local beds deposited by mainland rivers or, perhaps, by glacial streams, and that these gravels did not exist in Suffolk County, except possibly as offshore deposits and except for a small body of gravel, under the Bethpage clay beds, which has no water-supply importance.

Of other water horizons on Long Island, Professor Crosby's report shows that many successful wells, generally of small capacity, are found in the Magothy of the Cretaceous series within a belt along the north shore in Queens, Nassau, and Suffolk Counties, from Flushing to Port Jefferson, where the water-bearing gravels of this formation lie at elevations referred to sea level of + 70 to — 200 ft., and at a few localities on the south shore in Nassau County, where this gravel was found about 500 ft. below sea level. It was Professor Crosby's belief that the Magothy in Southern Suffolk County contains no gravel, and if it does exist in localities thus far unexplored, it lies beneath such thick beds of impervious sand and clay as to be cut off from the source of supply in the rains that fall on the surface of Long Island.

The lowest water horizon on Long Island, the Lloyd sand (Raritan), also of the Cretaceous series, lies still deeper than the Magothy gravel and not far

above the bed-rock. It is a more important horizon than the Magothy gravel and furnishes a large quantity of water at moderate depths of 200 to 400 ft. below sea level on the north shore of the Island, in Queens and Nassau Counties, from College Point to Huntington, and within a zone lying north of that in which wells in the Magothy occur. A few wells have been driven to the Lloyd sand in Southern Queens, where it is found at depths of 500 to 700 ft. below sea level. Professor Crosby pointed out that this horizon derives its supply, as does the Magothy gravel, from the Manhasset and outwash sands and gravels that fill the buried valley of Long Island Sound. If Lloyd sand occurs in Southern Suffolk County, it lies at still greater depths than in Southwestern Long Island, and it is more effectively cut off than the Magothy from the surface sources of fresh-water supply and is probably filled with salt water.

This work of the Board of Water Supply on Long Island is deserving of wider publicity. The knowledge gained there in regard to the deeper water horizons should prevent some unnecessary explorations in the future and the drilling of many useless wells.

ARTHUR S. TUTTLE,* M. AM. SOC. C. E.—The authors have omitted all reference to the work performed by them, a few years ago, in assembling, for convenient examination, records and specimens of all borings in New York City and vicinity. The nucleus of this collection consisted of the boring record made in connection with the development of the Catskill Water Supply, but it was reinforced by all other available data that were reliable. The result has been that a vast amount of data has been collected which should be of enormous value in the development of plans for engineering work in this locality. This collection of data is housed on the thirty-fourth floor of the Municipal Building, and it is in such form that any information desired can be readily obtained. It is hoped to add to this collection by securing similar data from work now in progress and from work to be undertaken in the future. The fact that this collection has been made and is under the care of the Chief Engineer of the Board of Estimate and Apportionment is probably not generally known, and the opportunity is taken, at this time, not only to advise that any one desiring such information will know where it can be secured, but also to invite any contributions to the collection, which are now or may be later available.

LOUIS L. TRIBUS,† M. AM. SOC. C. E.—The speaker has in mind two cases that might be of interest in showing the advantages of co-operation between the geologist and the engineer. He was sent to take charge of a reservoir that had been previously under construction for about a year. The earthern embankments were partly built and the bottom had been partly stripped. The plans contemplated a clay puddle, 2 ft. thick, as the bottom lining. Six or eight test pits had been dug, which showed a fair quality of loam and clay, with no rock appearing. However, when the bottom was fully excavated, it was found that about three-fourths of it was underlaid with limestone rock

* Chf. Engr., Board of Estimate and Apportionment, New York City.
† Cons. Engr. (Tribus & Massa), New York City.

having pockets 6 to 8 ft. deep. If a local geologist had been consulted or reasonable borings had been made, many thousands of dollars would have been saved. Concrete had to be used instead of clay puddle for the bottom lining.

Another case came into the speaker's practice a few years ago: A rather important dam had been partly constructed. When the bottom was first stripped, it appeared to be solid, but when the contractors commenced to excavate footings for the concrete, pockets were discovered large enough to hold small buildings, and washouts aided further in contributing knowledge. Owing to an almost complete absence of borings and lack of geological information, the owners spent several hundred thousands, and possibly, directly and indirectly, millions of dollars, to make good the deficiency.

Both the experiences mentioned are helpful in emphasizing the advantage of first obtaining geological data.

E. G. HAINES,* M. AM. SOC. C. E.—This paper differs from those usually presented before the Society. Primarily, it describes the work required on a rather extensive underground survey, and the information obtained therefrom. Such underground surveys are made for other engineering works, but they seldom cover as wide an area, nor are the investigations carried to as great a depth. In this case, the investigations were made largely by borings, often several hundred feet in depth (in some cases, as much as 1 000 ft.), whereas, for other engineering structures, a limited penetration into bed-rock is usually sufficient.

The paper presents the results from such borings verified by observations from the actual construction. Few engineers are familiar with the geological history, or even the geological structure, of the section on which they are employed. The speaker's attention has been called many times to that fact in connection with borings. He was once asked to examine a drawing called a boring sheet, which covered quite an extensive area in New York City. At the bottom of a number of holes, "white sandstone" had been recorded and this immediately aroused his suspicions, as he believed it to be limestone. The fact that the same material was shown at the bottom of a number of holes some distance apart indicated a general vein, and not boulders. It is difficult to understand how those who made the borings or recorded them on the sheet could have expected to find a vein of white sandstone enfolded, and in contact with Manhattan schist, which is a metamorphic rock folded and banded, and jointed in every direction, and eroded by glacial action. In this case, there was no excuse for an erroneous classification of the material, as a chemical and physical laboratory was available. The material in question was Dolomite, locally known as Inwood limestone and farther up the Hudson as Tuckahoe marble.

It may be held by some that this error in classification was of little importance, as the material was actually rock. That will not be conceded; the borings were made, not only for the information of the designers of an important structure, but also for contractors expected to bid on the work. At certain localities, the outcrop of Inwood limestone is disintegrated to such an extent that it is used as a building sand, whereas, in underground veins,

* Asst. Div. Engr., Transit Comm., New York City.

subjected to water and the acids in the soils, it is sometimes decomposed and resembles clay. Between these two extremes lies the more solid rock, which somewhat resembles sandstone.

The point the speaker wishes particularly to stress is this: If borings are made, the boring samples should be classified by some one competent to interpret them properly. This is not always the case. Many borings have been made in New York City and vicinity, the samples of which are incorrectly classified, particularly wash-boring samples, of which part of the finer material is lost in the process of obtaining the sample.

X. Henry Goodnough,* M. Am. Soc. C. E.—The first work of the geologist in connection with engineering work, that the speaker recalls, was many years ago on the investigation of ground-water supply in Eastern Massachusetts. The case was that of a town which had taken water from the ground near a river and was sued by a riparian owner for damages for diversion of the water. In that case, the town authorities succeeded in proving, with the aid of a geologist, that the stream came underground from the White Mountains, and escaped paying any damage for the water diverted.

The work with which the speaker has had to do recently has been chiefly in connection with studies for reservoirs in the valleys of some of smaller New England streams, tributaries of the Connecticut River. Here, one finds the usual conditions of streams in New England and the eastern part of the United States generally, deep gorges filled with sand and gravel and with rock on the sides. The determination of the location of the bottoms of these valleys is difficult and, in preliminary investigations, it is often important that the work shall be done without too great expense. In one of these valleys, it was found that the bottom was covered with boulders, some of which were very large, beneath 800 ft. of sand and gravel, but, fortunately, in that part of New England, there is no limestone, and none of the soft sandstone has been encountered in the localities examined. The aid of the geologist was very valuable in these investigations.

William W. Brush,† M. Am. Soc. C. E.—This paper is so complete that it does not leave much to be said in discussion, unless one goes outside the subject presented.

The speaker had the good fortune to be in charge of the studies for the City Aqueduct of the Catskill System. Extensive boring investigations were made so that these studies might be as complete as possible. In New York City, Dr. Berkey gave valuable assistance in determining the alignment of the pressure tunnel of the City Aqueduct. Owing to the location of this tunnel and the character of construction adopted, the traffic and life of the city were virtually unaffected during its construction. This is in striking contrast to the conditions in the streets when the many large pipe lines were laid for delivering the water to the smaller distributing mains.

Great difficulty was experienced in obtaining precise information regarding the rock formation underlying New York City from borings which had been

* Chf. Engr., Massachusetts State Dept. of Health, Boston, Mass.

† Deputy Chf. Engr., Bureau of Water Supply, Dept. of Water Supply, Gas and Electricity, New York City.

previously taken, as well as from other excavations. The borings made by the Board of Water Supply have been so recorded and the rock samples so marked that no difficulty should be experienced by those who, in the future, may wish to use them.

Dr. Berkey developed a map of the geology of Greater New York from information that he had obtained before the borings of the Board of Water Supply were commenced. The location of the various rock formations shown on this map differed materially from those that had been given on other maps. The borings subsequently made under Dr. Berkey's supervision for the Board of Water Supply, proved the accuracy of his deductions, although, in many instances, he had meager data from which to draw such conclusions. As a result of the work of the geologist, virtually no unnecessary borings were made.

The lesson to be drawn from the work on the City Aqueduct, as well as that on other parts of the Catskill System, is that the co-ordination of geological and engineering investigations can be used to great advantage and that such co-ordination should be utilized more frequently than has been the practice.

An experience in connection with the water supply system of Brooklyn is pertinent. The insistence on the part of certain persons that the water supply under Long Island comes from some drainage basin on the mainland and passes under Long Island Sound, caused the authorities of New York City to expend a large sum on developing a water supply based on that theory. Two pumping stations were built under a contract calling for the payment for water delivered, and both these stations have been abandoned. If the advice of a competent geologist had been sought, he would have supported the contention of the engineers, that on account of the geological formation an extensive water supply could not be transported from the mainland to Long Island.

The result of the combined study of the geologist and the engineer in the location and design of the City Aqueduct has been satisfactory as to operation. The speaker has been connected with the operation of the Catskill System since it was placed in service in 1917. The pressure tunnel which extends under the Bronx and Manhattan, to the two terminal shafts in Brooklyn, has met all expectations in delivering a large volume of water without serious leakage. Two or three small leaks have developed in the basement of buildings, but the flow from these leaks has decreased each year, and it has not been serious at any time.

THOMAS H. WIGGIN,* M. AM. SOC. C. E.—The Engineering Profession is indebted to the authors for the record of the geological investigations made for the Catskill works. They have properly emphasized the perfect co-operation which existed between the engineers and the geologists and which makes this work a good example of the proper method of conducting such investigations. Recognition is also due to the broad and economic policy of the former Chief Engineer, J. Waldo Smith, M. Am. Soc. C. E., supported by

* Cons. Engr., New York City.

the Commissioners of the Board of Water Supply and by the engineering advisory staff, which made such a thorough investigation possible. Mining engineers have long made good use of geological investigations and core borings. Engineers in other branches have also made increasing use of these aids, but have generally confined this practice to special problems.

One of the earliest examples of a thorough geological investigation was that made for the Wachusett Dam, in Massachusetts, by Professor W. O. Crosby, for the late Frederic P. Stearns, Past-President, Am. Soc. C. E., then Chief Engineer of the Massachusetts Metropolitan Water-Works and afterward Consulting Engineer on the Catskill works. This investigation was made a few years prior to 1900. On the same works, there was a tunnel the investigations for which were less complete. The portal was in rock and it was assumed that, farther on, the rock was higher and that, therefore, the tunnel would be in rock throughout. As a matter of fact, the rock was lower beyond the portal and for about 1 000 ft. remained at approximately mid-height of the tunnel, thus greatly increasing the cost and making an allowance to the contractor necessary in order to enable him to finish the work.

The so-called New Croton Aqueduct, beneath the Harlem River, penetrated rotten rock in a narrow crush zone and had to be placed at a lower elevation. As regards the number and the location of the borings, the rock had been well explored. The importance of the narrow crush zone, however, as it was apparently disclosed by the boring which traversed it, was underestimated as could easily be done under the circumstances. The disaster that occurred in 1908 when the Loetschberg Tunnel, in Switzerland, was under construction, is still comparatively fresh in the minds of engineers. Owing to reliance on prognostications of geologists, unconfirmed by borings, a zone of disintegrated, wet, and flowing rock débris, thought by the geologists to terminate well above the tunnel, was unexpectedly penetrated, and the tunnel was filled so quickly that 25 men were killed.

The Catskill works had all these examples and others from which to profit and they were heeded. It was realized that a new element was injected into the investigations by the unprecedently high unbalanced pressure of 200 to 400 ft. that would exist in the pressure tunnels when they were in service. The speaker had charge of the design of these tunnels and it was his privilege, in the early stages of the geological investigations, to aid the geologists in visualizing these unusual conditions which differed so greatly from those in the ordinary mining or academic problems.

The Rondout Pressure Tunnel presented one of the most complicated geological problems. Preliminary estimates indicated that the cost of the pressure tunnel would be about the same as that of steel pipes. As it developed later, however, steel pipes would have been somewhat cheaper and, if the Catskill Aqueduct type of concrete-covered, mortar-lined, steel pipe, later suggested by the speaker and used for siphons where the geology was unfavorable for tunnels, had then been evolved, it is possible that such pipes would have been chosen instead of the tunnel, as the tunnel was expected to be wet in the section penetrating the Binnewater sandstone and High Falls shale. There is no reason to regret, however, that the more con-

veniently operated and probably more permanent tunnel was built. The geologists and the engineers were brought into definite contact first in studies of the Rondout Pressure Tunnel when the attempt was made to translate the generally qualitative conceptions of the geologist into the quantitative results necessary to estimate the quantity of water to be pumped during construction, lengths of tunnel that would require timbering, possibilities of outward leakage, etc. The stratification of the rock shown on the tunnel profile, which formed the basis of the studies for depth of tunnel, was mainly the result of close co-operation between the Field Division Engineer, Lazarus White, M. Am. Soc. C. E., his Principal Assistant, J. P. Hogan, M. Am. Soc. C. E., and Professor Crosby, Consulting Geologist, in placing and interpreting borings. Professor Crosby and the speaker subsequently discussed the factors affecting the proper depth of tunnel. Professor Crosby's long experience in mines gave him a definite conception as to the probable leakage, and as the result of this conference, a part of the tunnel was placed 100 ft. deeper than had been previously contemplated. The rate of leakage into this tunnel on the incline where the porous Binnewater sandstone and High Falls shale were penetrated, was somewhat underestimated, but the difficulty in removing the water and of obtaining a tight tunnel was perhaps over-estimated. After the experience with wet ground in the Rondout Tunnel, the pressure tunnels to be built subsequently were viewed with less apprehension both by the engineers and the bidding contractors.

Certain pure limestone strata traversed by the Rondout Siphon caused anxiety to the designers, on account of the experience in the Thirlmere Aqueduct, in England, where the concrete made of similar limestone dissolved badly. As the authors state, this limestone was not used in the concrete lining. The rock through which the tunnel passes is still subject to solution, but reliance was placed in a good lining and careful grouting to reduce the circulation to a negligible quantity. Furthermore, the small carbon dioxide content in the water and its reduction by aeration at Ashokan Reservoir will minimize the power of the water to dissolve the limestone. The tunnel is becoming tighter all the time.

The Wallkill Siphon offered no geological difficulties. It was entirely in shale and rightly expected to be largely free from inward leakage. After the rock profile had been determined by a sufficient number of borings, the only important problem was the necessary depth of tunnel below the rock surface. This was a pioneer line of thought with respect to such large unbalanced pressures.

One criterion applied by the designing engineers was that the depth should be such that the weight of earth and rock above the tunnel would offset the upward unbalanced water pressure, estimated as the height of a column from the hydraulic gradient to the level of ground-water. This condition, however, might be met by a deep cover of earth and a shallow cover of rock. Stability and water-tightness demanded a substantial thickness of rock; even a thick rock cover had its possible weakness, as a laminated rock

could conceivably fail by the accumulation of full pressure in a horizontal seam near the top. A failure of this kind occurred later at the shaft of the City Tunnel in Bryant Park, New York City. The minimum depth of pressure tunnel below the top of sound rock was decided as 150 ft. This was an arbitrary thickness suggested by the speaker and accepted by the Chief Engineer and his advisory staff, and, thereafter, became a standard for fixing the depth of other pressure tunnels on the Catskill System, including the City Tunnel.

Moodna Siphon was partly in shale generally like that penetrated by the Wallkill Siphon and partly in granodiorite like that through which the Hudson Siphon was constructed. As described by the authors, the stretch in shale was suspected of harboring a buried gorge of an ancient stream. Many borings were made in the search for that gorge, some of which were only about 150 ft. apart. Luckily no gorge existed, although the reason that the ancient stream left such a broad flat floor in such easy shale digging is still somewhat puzzling.

Borings in the river to discover the Hudson Gorge were unsuccessful, although one hole, beginning with an 18-in. and ending with a 2-in. casing, penetrated more than 760 ft. It took more than a year to put this boring down, and it petered out as boulder after boulder required successive reductions in the size of the casing. At about that time, the speaker was sent West to investigate inclined shafts in the Michigan copper country. This investigation was apropos of the proposal to sink an incline from each side of the Hudson River toward the center, maintaining each incline at a safe distance below the rock surface by making pilot borings from the incline ahead to the rock surface. The speaker gained considerable information about long inclined borings, and it was decided, instead, to make such borings from the vertical shafts already started. Fig. 12 shows how this was done, although it does not explain why two sets of borings were needed. The records of long inclined borings for Michigan mines showed that they curved upward considerably, as shown by Fig. 19. It had been found that close clearances in the first two boring rods, that is, a small difference between the size of hole as determined by the setting of the diamonds and the diameter of rods, high rotary speeds, and light rod pressure resulted in less curvature, but did not eliminate it. In the specifications for the long inclined Hudson borings, a generous size of hole and all the previously mentioned aids to straightness were used. The lower holes shown in Fig. 12 were drilled first. They were expected to curve upward so as to occupy, at the center of the river, a position not much deeper than that explored by the second or upper set of holes. They remained practically straight, however, and went too low, and the upper pair of holes, therefore, was bored to explore the rock higher up and to allow the tunnel to be located at a higher elevation, which was done.

Another consideration in connection with the investigation of the Hudson Siphon, which, in a lesser measure, is pertinent to the other siphons, is the possibility of a buried falls just below the line of borings. It is conceivable that a thin wall of rock might be left on the down-stream side of

the tunnel at such a falls, even if the vertical rock cover was sufficient. The speaker does not recall that such a falls was then regarded as a geological impossibility, although he notes that evidence now available relating to the Hudson Gorge southerly, is regarded by the authors as proving an overdeepening effect rather than a falls at Storm King. The falls was always regarded as a remote possibility and did not affect the profile.

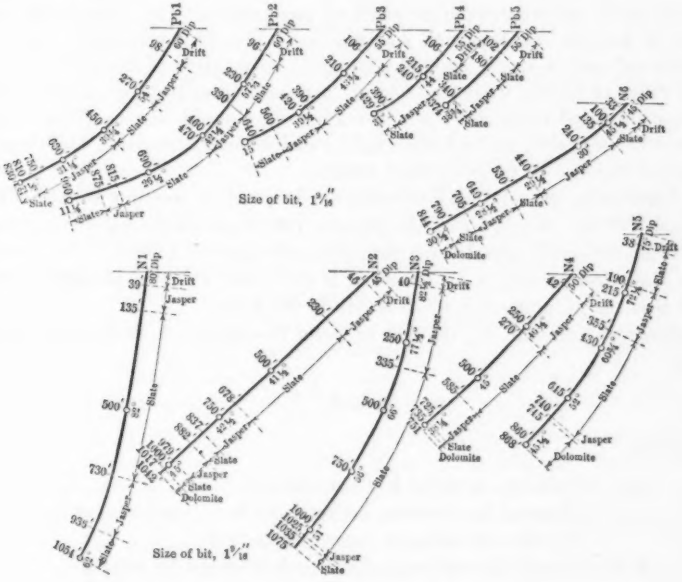

Fig 19.

In describing repairs to the Eastview Tunnel, the authors omitted to state that a water-proofing diaphragm, consisting of three thicknesses of cotton duck impregnated and coated with asphalt in the usual way for such waterproofing, was placed between the original concrete lining and the new brick lining. It was hoped thus to exclude the acid water from the new lining.

JOEL D. JUSTIN,* M. AM. SOC. C. E. (by letter).—The writer was particularly interested in the authors' description of the geologic conditions at the sites of the Gilboa and Devasego Falls Dams. It would be most interesting to learn more of the considerations which led to the abandonment of the Devasego Falls site, where topographical conditions indicated much cheaper structures than those required at the adopted Gilboa site.

The authors state that the ridge of glacial drift which forms in part a natural dam across the valley of the Schoharie at this place, contains a pervious layer about 1 000 ft. wide, 1 200 ft. long, and 30 ft. deep. The top of this pervious stratum is stated to be at about Elevation 1 100.

* With Day & Zimmerman, Holtwood, Pa.

Through the work of Allen Hazen, M. Am. Soc. C. E., Professor Slichter, and other experimenters, the laws of flowing water through pervious soils, sands, and gravels are quite well known. With a thorough sub-surface investigation, such as that at the Devasego Falls site, it is possible to predict, within reasonable limits, the leakage through such a stratum. It would also be possible to determine whether the velocity of any water that might issue to the surface at the down-stream end of the pervious stratum would be sufficient to move any of the constituent particles of the stratum. The value of the water lost by leakage through such stratum could also be determined. With the results of such a study available, it would be possible to determine whether this ridge of glacial drift could safely and economically be utilized as a part of the proposed earth dam, whether a cut-off through the pervious stratum would be desirable, and whether safety and economy required the abandonment of the site in favor of some other.

Apparently, the total head of water on the pervious stratum would not have exceeded 60 ft. Assume that the stratum extends from the up-stream face of the ridge through to the down-stream side, a distance of 1 200 ft. Also, assume that the effective size of the material is 0.10 mm., that the porosity is 32%, and that the ground-water temperature is 60° Fahr.

Slichter's formula* for the flow of water through sands and soils is, as follows:

$$q = K\frac{p\ s}{h}$$

in which,

q = discharge, in cubic feet per minute;
p = difference in elevation between the two points considered or difference in pressure measured in feet;
h = distance through soil along path followed by water;
s = area of saturated cross-section of soil considered; and
K = the transmission constant.

The factor, K, is always the same for the same soil at the same temperature. The transmission constant, as defined by Slichter, is "the quantity of water that is transmitted in unit time through a cylinder of the soil of unit length and unit cross-section under unit difference in head."

The proper transmission constant for the given effective size and porosity, originally determined experimentally, is 0.00405, as obtained from Table 1 of *Water Supply Paper No. 67.*

By making the proper substitutions in Slichter's formula,

$$q = \frac{0.00405 \times 60 \times 1\,000 \times 30}{1\,200}$$

$$= 6 \text{ cu. ft. per min.}$$

If instead of the effective size being assumed as 0.10 mm., it had been assumed as 0.35 mm. (about the size of filter sand), computations would have

* *Water Supply Paper No. 67,* U. S. Geological Survey.

indicated a leakage of a little more than 1 cu. ft. per sec. under the assumed conditions.

The velocity of the water flowing through the soil would be obtained by dividing q by the area of the water passages, or,

$$V = \frac{q}{s\,P}$$

in which,

V = velocity, in feet per minute;
q = discharge, in cubic feet per minute;
s = area of cross-section of soil through which water is flowing; and
P = percentage of porosity expressed as a decimal.

Thus, with the computed discharge of 6 cu. ft. per min., $V = 0.00063$ ft. per min., or less than 1.0 ft. per day, which is less than that required to move any particles of the assumed material. These computations are merely illustrative. No doubt a study along the lines herein discussed was made by the engineers of the Board of Water Supply. It is to be hoped that the details of the investigation and study of the Devasego Falls site will be described, as they would be of great value to engineers having similar problems.

In some sections of the United States, impervious foundations for earth dams are not available and some earth dams must be built of quite pervious material. Where such conditions have been found and properly interpreted by thorough sub-surface investigations, safe dams have been designed and built.

JAMES F. KEMP,* ESQ. (by letter).—This valuable paper summarizes the unusual experience gained in the application of geological investigations to a great engineering problem. The reading of it recalls many lessons which were driven home to those who shared in the early work; and, at least, one geological principle which to that time had not been appreciated at its true value in the United States. Geologists no less than engineers have profited by the work of the Catskill Aqueduct. In discussion, the writer would like to direct attention to one or two of these especial problems.

The selection of the most advantageous place at which to cross the Hudson River was one of the early and, also, one of the most important problems. As noted in the paper, a number of tentative explorations were made above and below the Storm King crossing which was finally chosen. The explorations were made by wash borings, and profiles of the bed-rock bottom based on the results were prepared. The conclusion of those in charge, however, was that by this method the drill might easily come to rest on a large boulder and furnish unreliable evidence regarding the bed-rock unless the borings were checked by the diamond drill or the percussion drill to a depth sufficient, from the thickness and the nature of the rock penetrated, to preclude a boulder. It was learned that, for deep land borings or for borings under a river or other body of water, unchecked wash borings are of little value, especially in glaciated regions.

The geologists also had in mind the importance of finding a crossing for the pressure tunnel where there would be no faults. Breaks in the strata meant

* Prof. of Geology, Columbia Univ., New York City.

places of weakness which, under earthquake stress, might also be places of movement. Unless the selected location should prove practically impossible because of other considerations, such as disadvantageous approach, they desired to decide on a crossing without these structural lines of disturbance. Investigations led to the realization that there were many faults in the part of the Hudson Valley under exploration. Contrary, moreover, to the general belief regarding faults, those discovered were usually not of the normal, but of the reverse, type, and indicated that frequent over-thrusts had been produced in the past. The later and more detailed studies of Dr. Berkey in the West Point Quadrangle and field trips with students in other areas of this region, have abundantly corroborated the early experience on the Aqueduct.

Geological considerations favored a crossing where the same kind of rock was exposed on both banks and presumably continuous beneath the river. The Storm King crossing with its granite on both banks received early preference; but, in so narrow a gorge, one could not ignore the possibility or even the probability of a fault as the line of weakness which originally located the drainage. It was fortunate, however, that subsequent exploration, disclosed no fault beneath the middle and west side and only a small fault near the east bank, which fault fortunately passed upward into Breakneck Mountain and not into the river gravels and silts. Elsewhere, along the course of the Aqueduct many faults and weak crushed zones were found, and from the trouble caused by them, as described in the paper, they abundantly justified the original apprehensions.

The wash borings in the tentatively explored crossings above the Highlands disclosed no reason to expect unusual depth to bed-rock in the narrow Storm King Pass. Farther up stream the valuable record of the exploration to bed-rock at the Poughkeepsie Bridge, which were contributed by John F. O'Rourke, M. Am. Soc. C. E., in 1888,* also indicated the bed-rock from shore to shore, at about 140 ft. below high-water mark. The natural inference was that the granite at Storm King and Breakneck Mountain, which extended across the 2 000 ft. of river and which was the hardest rock in the stream from the Adirondacks to Cornwall, would furnish a gigantic riffle rather than an unusually deep depression. In the earliest work, this consideration gave added support to the choice of the Storm King site for the pressure tunnel. The reasoning that would have been followed at that time by practically every American geologist was that the bed-rock channel had been eroded by running water; that there must be a down grade to the sea; and that the land must have stood higher than it does at present with reference to sea level, so that the rivers could drain off. A progressively deeper channel was expected through the lower reaches of the river past New York City and out beneath the present ocean bottom. Geologists knew of the off-shore gorge of the Hudson, in the Continental Shelf, as it had been described years before,† but they were not

* "The Construction of the Poughkeepsie Bridge", *Transactions*, Am. Soc. C. E., Vol. XVIII (1888), pp. 199–215, especially p. 202.

† A. Lindenkohl, "Geology of the Sea-Bottom in the Approaches to New York Bay", *American Journal of Science*, Vol. 29, p. 475 (1885), and "Notes on the Submarine Channel of the Hudson River, etc.", *loc. cit.*, Vol. 41, p. 489 (1889); and J. W. Spencer, "Submarine Great Canyon of the Hudson River," *loc. cit.*, January, 1905, pp. 1–15.

prepared for the great depth, 800 ft. ±, which the drill subsequently revealed. This great depth led them to two possible conclusions, namely, the existence of a deep narrow gorge, deepening constantly to the south, past New York City to the sea, or, an over-deepening of the gorge at Storm King by sub-glacial erosion and the gradual rise of the bed-rock to and beyond Manhattan Island, as the southward moving glacier grew thinner and thinner and less effective as it approached the Terminal Moraine. The writer is of the opinion that the latter explanation is correct. Above the Storm King crossing is the broad open bay of Newburgh, once undoubtedly filled with southwardly moving ice. The abrupt front of the Highlands crowded all the ice below the tops of the mountains into the narrow Storm King Gorge and created conditions exceptionally favorable for sub-glacial scouring and erosion. Access has since been gained to the records of the borings made by the Pennsylvania Railroad Company opposite 33d Street, Manhattan, for its tubes, but there is a gap of 1200 ft. in mid-stream in which it cannot positively be stated that a deep narrow gorge may not exist, although that seems to be unlikely.* The bed-rock on the west side of the interval was 301 ft. below the surface, and that on its east side 287 ft. Nowhere else was the bed-rock so deep. Geologists still hope that some time a diamond drill boring may penetrate and demonstrate the bed-rock in mid-stream. At present, however, it may be stated that the Storm King crossing and its great depth to bed-rock beneath the river has convinced the writer and many other American geologists of the soundness of the belief in the sub-glacial erosion by ice.

The borings in minor stream bottoms in the approaches to the Hudson River and the departures from it, and for the tentative sites for the great Ashokan Dam invariably revealed buried bed-rock channels, sometimes coincident with the general location of the present stream, and sometimes at distances from it. Geologists have thus been able to reconstruct an interesting system of pre-glacial drainage active when the land stood higher than it does to-day with reference to the sea level.†

The geological sections in the Hudson Valley, in the Wallkill Valley, and in the Upper Esopus Valley, are comparatively simple; but when the Rondout Valley is crossed, the section both in number of formations and in faulting becomes exceedingly complex. It was explored, therefore, with great thoroughness by the drill, and the results were accurately drawn in profile before bids for the sub-divisions of the pressure tunnel were invited. Contractors were thus enabled to bid with full knowledge of what they would find regarding the depth and character of rock. The geologists realized that the Binnewater sandstone was practically certain to be a wet formation. The precaution was

* In 1910, these data were placed in the hands of the late G. Sherburne Rogers, at the time one of the graduate students of Columbia University, and was the basis of the paper by him, entitled "The Character of the Hudson Gorge at New York City," which was published in the *School of Mines Quarterly*, November, 1910, pp. 26–42.

† "Buried Channels Beneath the Hudson and Its Tributaries," by the writer, *American Journal of Science*, October, 1908, pp. 301–323; "Geology of the New York City Aqueduct," by Charles P. Berkey, *Bulletin 146*, New York State Museum, 1911, which gives numerous local details. For a review of buried channels elsewhere in the region, see "Buried Channels in the Northeastern States," by the writer, *Proceedings*, Wyoming Historical and Geological Soc. of Wilkes-Barre, Pa., Vol. 14, pp. 1–20 (1913). These phenomena are of much interest to civil engineers in connection with dam sites, and many problems of water supply.

thus adopted by the engineers of dipping down with the tunnel as they neared this sandstone and, after installing pumps, to tap the sandstone on the up grade. The water which rushed in, was thus promptly cared for, and no delay in the work resulted.

Many other individual problems are admirably set forth by the authors, to whom engineers and geologists everywhere are under a great debt. The problems selected for discussion by the writer are those, however, which occur to him as of especial interest and importance to both groups.

THADDEUS MERRIMAN,* M. AM. SOC. C. E. (by letter).—Attention has been called by Mr. Justin to the general question of underground flow, and he has expressed a wish to know what theoretical investigations, if any, were made in order to determine the feasibility of the Devasego Dam site. The controlling reasons for the adoption of the site at Gilboa in preference to that at Devasego were:

First.—Sub-surface investigations at Gilboa showed this site to be much the better. No uncertainties such as those disclosed at Devasego were revealed by the borings.

Second.—The Gilboa site would furnish a larger reservoir with more storage and, at the same time, increase the available drainage area from 243 to 314 sq. miles.

The situation at the Devasego site was as follows: As stated by the authors, the preliminary borings had disclosed the existence of a large body of doubtful material about 30 ft. thick and 1 200 ft. wide. In order to determine the perviousness of this ground, a number of tests were made by pumping water into the drill casings. By noting the pressure at the top of the casing, the quantity of water pumped, and the rise of the ground-water table at other holes in the vicinity, it was possible to reach reasonable conclusions as to the continuity of the porous zone and its water-carrying capacity.

Twelve of these tests were made after the drill casings had been lifted and the drill holes in the rock had been completely filled with clay in order to prevent the escape of water through the rock joints. The results of these tests are summarized in Table 1.

TABLE 1.

Test No.	Length of test, in hours.	Rate of pumping, in gallons per minute.	Pressure at top of drill hole, in pounds per square inch.	Number of responses in other holes.

* Chf. Engr., Board of Water Supply, City of New York.

The tests, summarized in Table 1, showed that the doubtful material was exceedingly porous and could not be depended on alone to serve as part of any dam. For instance, Test No. 7 showed that 89 gal. per min., pumped for 51 hours—a total of 272 000 gal.—raised the elevation of the water-table in eleven other holes an average of 0.46 ft. over an area of about 15 acres. The most distant hole in which a rise was noted was 900 ft. from that into which the water was pumped. Although these tests did not quantitatively disclose the capacity of this material for carrying water, they did show that at many points, with little or no resistance, it would take from 80 to 130 gal. of water per min. through a 2½-in. pipe, and that this water would flow freely for long distances and over large areas.

Although the methods suggested by Mr. Justin may be applicable to cases in which sand and gravel have been uniformly laid down, they cannot be adapted to locations such as that at Devasego, or, in fact, to any location in a glacial deposit, unless the facts as to the uniformity of that deposit are known.

The problem at Devasego was generally similar to that described by the authors at "The Tongore Alternative Site" of the Ashokan Reservoir. The preliminary borings at this alternative site disclosed conditions which were interpreted as indicating a doubtful and undesirable situation. The site, however, offered such other advantages that further examination seemed to be desirable. A shaft, therefore, was sunk to the material which had been shown by the borings to be pervious. In commenting on the conditions at the time (1906), Dr. Berkey wrote as follows:

"The conditions reported in the new large shaft (Tongore) in the gravel beds now being penetrated, *i. e.*, at first 'no water', and then a little deeper an 'abundant flow,' I interpret as follows: It is not an isolated pocket or lens, else it would have carried water full from the first. It must be a fairly continuous porous zone with large feeding connections else it would run dry, and with easy discharge, else it would have risen above the first gravels. Therefore, it must be a rather well marked subterranean water passage or perhaps a porous zone of considerable extent. Such conditions it seems to me make an impervious core wall to bed-rock a necessity, and its construction a matter of considerable difficulty. In this site, because of the small cross-section of the ridge, there is little chance for the interlocking of layers or the blocking of the porous ones by a till barrier."

These two cases serve to illustrate the necessity of supplementing the results obtained by the ordinary wash-borings whenever the conditions are doubtful. They also serve to show that theoretical considerations alone are not to be depended on as trustworthy guides.

CHARLES P. BERKEY,* ESQ., and JAMES F. SANBORN,† M. AM. SOC. C. E. (by letter).—The writers wish to express their appreciation of the comments that have been made by the engineers who have contributed to the discussion. Altogether important contributions have been made, and the writers willingly accept the corrections, criticisms, and additions.

In the beginning, it would have been possible to increase greatly the scope and detail of the paper. Many items of more than local or personal interest were deliberately omitted in order to keep the paper within moderate length

* Prof. of Geology, Columbia Univ., New York City.
† Cons. Engr., New York City.

and also to reserve the available space for more careful attention to certain items that seem to illustrate better its purpose.

The writers have held strictly to the plan of laying a rather simple foundation picture of the nature of the enterprise, and the conditions under which it had to be developed. Following that, the major instructive geologic incidents and problems that seemed to promise a contribution of possible value to the Engineering Profession were treated. It was believed that examples of the interrelation and interdependence of geologic and engineering factors were exhibited so well in certain parts of this project that they might serve a good purpose in illustrating appropriate methods, splendidly effective co-operation, and successful solutions of many obscure and somewhat baffling natural conditions.

It is the writers' belief, based on a great many years of observation, that neglect of geologic factors or inadequate study of them is a common fault in a majority of engineering undertakings. Many serious blunders may be traced to this as a fundamental cause, and it is hoped that the illustrations given in connection with an important project, such as the Catskill Water Supply, which is now known to have been very successfully conducted, may be serviceable. There is no desire to over-emphasize the contribution of geology to that success; that it was a contribution of no little importance is so generally attested by the opinions of the engineers in charge and by the results secured, that the writers feel fully justified in stating the facts and in separating the principal geologic problems as found in this work from the obscuring mass of other problems and data, so that one may the more clearly see their bearing.

The writers do not assume to claim that a geological study is the cure for all difficulties. Neither do they assume to suggest that geologic opinion is to take the place of properly organized exploration. This is a mistake commonly made. It is just as extreme and unreasonable as the attempt to ignore the geologic factors. It is not unusual to hear engineers say that even if a geologist is employed explorations must be made, as if that was some sort of legitimate reflection on the geologist and sufficient excuse for the engineer. Yet, that is exactly what should be done in the average engineering case. If he is competent, the geologist can indicate not only what kinds of explorations should be made, but also where they must be made to accomplish the most useful returns in the most economical way. He should be able, also, if he is familiar with the needs of the engineer, to interpret the data observable in the field and obtained by exploration, more logically and more reliably than one who is not thus trained. The geologist, therefore, should not be regarded as a substitute for exploration, or an excuse for loose methods, but an interpreter of geologic conditions, an aid in successful investigation, and a critical adviser in the matter of design, methods, and contracts that have to do with construction in the ground.

Many engineers of long experience become familiar with physical conditions and the laws of ground behavior. They are normally close observers and rigid reasoners and are exceedingly cautious in drawing conclusions. They are preeminently qualified in these respects for just such kind of work as falls also to the geologist; and it often happens that little more than support can be

given to the conclusions already reached by such engineers. It so happens, however, that it is not usually possible for a man in one great field of endeavor to become a master of other, even closely related, lines. He cannot feel certain that all its possibilities are met and that his conclusions are reliable. To such a man, a competent geologist can render real service. It sometimes happens that an engineer is not well enough informed or experienced to appreciate what the problem is, or even that there is a problem at all or that it can be solved, and, for this reason, among others, additional opinion is not asked. Sometimes, one has to ask permission to help such men, or one is asked to explain the cause of the trouble after it is too late for advice to serve any purpose.

The ideal situation is one in which the engineer, already comparatively well grounded in all the major features of the problem to be encountered, is still able to appreciate that a fuller or more critical study might materially improve the chances of success, or allow the design to be modified better to suit the conditions, make the contracts more definite, secure more economical treatment, or conduct the work on safer lines. Wherever this broad view is taken, and adequate consultation privileges are conferred on a competent, experienced geologist who appreciates the point of view and purpose of the engineer and will confine himself to the practical questions of the case, material service can be rendered in phases of the undertaking that cannot be reached any other way.

In an important case, where all the facts and conditions are not perfectly clear, the geologist should know enough not to give a final opinion without additional exploratory evidence; and the engineer should be wise enough not to treat an opinion as if it was a proven fact and then blame the geologist for mistakes which belong to both. The average responsible engineer has been found by the writers to be an unusually intelligent man who readily appreciates the distinction between facts of observation and inferences, and between conclusions based on close, logical reasoning and hypotheses based on more or less incomplete or inadequate data. All these things have to be dealt with, however, and it is peculiarly the province of geology to deal with many of the less conclusive hypotheses, not at all because the geologist wishes it to be so, or because it is his habit of mind, but simply because many underground conditions are obscure and because only a few of the many needed facts in a given case can be found by any method at any one's command. Thus, the geologist does the best he can with what he can get, in the belief that this, also, will be helpful.

The paper has been written largely to explain and illustrate that part of the work on the Catskill Aqueduct which normally came under the eye of the advisory engineering geologist. There is like work to be done by some one in every project of a similar nature. The writers are certain that a greater amount of such help should be obtained in most projects having to do with the ground, and they hope that the illustrations given by them, together with the comment made by those who have so liberally and instructively discussed the paper, may help enforce this observation and thus make the contribution something of educational value to younger men who, in the future, are to be responsible for large public undertakings.

Paper No. 1510

SOME NOTES ON THE LOCATION AND CONSTRUCTION OF LOCKS AND MOVABLE DAMS ON THE OHIO RIVER, WITH PARTICULAR REFERENCE TO OHIO RIVER DAM NO. 18.

By William M. Hall,* M. Am. Soc. C. E.

With Discussion by Messrs. Thomas P. Roberts, Earl I. Brown, William W. Harts, L. M. Adams, C. I. Grimm, B. F. Thomas, Malcolm Elliott, Frederick B. Duis, W. H. McAlpine, Gardner S. Williams, Morris Knowles, and William M. Hall.

Synopsis

This paper presents briefly a history of the improvement of navigation on the Ohio River.

To maintain a navigable depth during the low stages of the river and to retard as little as possible open-river navigation during the high stages, movable dams with locks were constructed.

The considerations influencing the location, design, and construction of these dams, together with some notes on operation, are discussed by the writer, with particular reference to Ohio River Dam No. 18.

Introduction

Historical.—The first work of aiding and improving navigation on the Ohio River consisted in the removal of snags, boulders, and bars, the building of dams for closing the smaller and less important channels at islands, the building of spur-dikes to narrow the channel at some of the bars and shoals, and, in later years, the dredging of shoals and the building of ice piers to protect boats from floating ice when in "harbors" or protected places alongshore. All these methods failed to maintain a minimum depth of 3 ft.

* Parkersburg, W. Va.

for navigation during dry seasons and, as a last resort, the more expensive method of improvement with locks and dams was undertaken.

The first appropriation by the National Government for the Ohio River was made in 1824, and the improvement of the river by the open-channel method was commenced in 1827. From 1825 to 1830, a private company, under a charter from the State of Kentucky, built the Louisville and Portland Lock Canal for carrying traffic around the Falls of the Ohio (Mile 604 below the head). On February 8th, 1885, the United States acquired the stock of the Company and thereafter operated and improved the canal.

In 1870, the late W. Milnor Roberts, Past-President, Am. Soc. C. E., made the first written recommendation of record for changing the method of navigation to that of locks and movable dams. In 1874, the late Maj. W. E. Merrill, Corps of Engineers, U. S. A., M. Am. Soc. C. E., recommended the improvement of the upper river from Pittsburgh, Pa., to Wheeling, W. Va., by a system of thirteen locks and movable dams. The River and Harbor Act of March 3d, 1875, appropriated $100 000 for starting construction on Lock and Dam No. 1 at the head of Davis Island, about five miles below Pittsburgh, which lock and dam was opened for operation on October 7th, 1885.

Since that time, by enactments at irregular intervals, locks and dams to No. 39, inclusive (Mile 529), and Nos. 41, 43, 44, 45, and 48, have been placed under construction. Of these locks and dams, thirty-three have been placed in operation.

Physical Features.—The Ohio River (Fig. 1) is formed by the confluence of the Allegheny and the Monongahela Rivers in Western Pennsylvania. It flows in a general southwesterly direction and empties into the Mississippi River, the two, near their confluence, forming the southern boundary of Illinois. The total length of the Ohio is 968 miles, and it has a drainage area of 203 900 sq. miles. The discharge of the head varies from about 1 600 sec-ft. at low water to 440 000 sec-ft. during flood, and, similarly, at the mouth, from 27 500 to 1 500 000 sec-ft. At low water, the average fall is, as follows:

	Miles.	Inches per mile.
Pittsburgh to Wheeling.....	90	11½
Wheeling to Cincinnati.....	378	5½
Cincinnati to mouth*.....	500	4

The width of the channel increases gradually from about 850 ft. near the head to 5 900 ft. at a point 22 miles above the mouth. The extreme stages of the river as given by gauge records at various points are, as follows:

Pittsburgh, Pa.....	(Mile 1),	highest stage	35.5 ft.	in	1907
Parkersburg, W. Va..	(" 186),	" "	58.9 "	"	1913
Cincinnati, Ohio.....	(" 469),	" "	71.1 "	"	1884
Louisville, Ky., below Falls.....	(" 604),	" "	70.6 "	"	1884
Cairo, Ill.....	(" 968),	" "	54.8 "	"	1913

* Including 26 ft. in 2 miles of the Louisville Falls.

Extent as Water Route.—The inland water route for greatest tonnage and importance in the development of the United States is that from the easterly end of Lake Erie to the westerly end of Lake Superior. Second to it, is the route from Western Pennsylvania down the Ohio and Mississippi Rivers to the Gulf of Mexico. As Professor Hurlbert has well said in his history:* "From whatever standpoint one views the Ohio River, it has a most interesting history; but of them all none is more attractive or important than that from which it appears as a strategic avenue of National expansion."

In the settling and building of the Middle West, the Ohio River was one of the great highways, and when National, rational, and wise traffic regulations have been adopted, it will continue to exert a great influence on traffic and the upbuilding of the country through which it flows. Possibly no subject of National policy requiring large expenditure has been more abused, distorted, and used for political and private ends, during the past fifty years, than the river and harbor appropriations. Notwithstanding that condition, the project as wrought out for improving this great river appears creditable to the country and to the Governmental agents in charge. From the viewpoint of the engineer employed on the improvement now projected and in progress during the past two decades, it is no less interesting than it was to the explorer and pioneer, one to two centuries ago.

The mileage of navigable water in the Ohio River System is about as follows:

Ohio River	968
Allegheny River	38
Monongahela River	130
Muskingum River	90
Little Kanawha River	108
Great Kanawha River	90
Big Sandy River	27
Carried forward	1451

Cumberland River	518
Tennessee River	650
Total	3 271

The Ohio River and the Great Lakes Systems will probably be connected between Pittsburgh and Lake Erie and, possibly, across Illinois, thereby making an inland system of great National importance. These projects are now being strongly advocated.

Commerce.—The commerce of the Ohio River is divided into two general classes: Package freight, loaded on the decks of steam and gasoline boats, and bulk freight, such as coal, timber, iron, and petroleum products, moved by barges.

The boats that carry package freight and passengers range in size from the diminutive gasoline motor-boat to steamboats 320 ft. in length. The barge freight is carried largely on coal boats about 26 ft. wide by 130 ft. long and from 8 to 12 ft. deep.

The fluctuation in tonnage is shown in the Annual Reports of the Chief of Engineers, U. S. A., and is indicated by the extract given in Table 2.

Since 1894, the greatest decrease in tonnage has been principally in the coal from Pittsburgh down stream. The freight moved in 1894 was about 3 500 000 tons, of which more than 3 000 000 tons were of coal. Within the past decade the shipment of coal from the Pittsburgh District down stream has been stopped almost entirely by the adoption of a policy to conserve it

for home consumption. This policy cut off at one stroke about one-half the tonnage of the river.

The writer thinks that the building of locks and dams is not rapidly increasing the tonnage, nor will it do so for package freight until the policy in reference to its movement is more satisfactorily administered. Under present methods of operation, no company carrying passengers and freight in less than barge loads, has built up a trade and held it at a fair and profitable rate.

In 1909, the Receiver of the Pittsburgh and Cincinnati Packet Line, the largest line on the upper river, gave the following reasons for this financial condition:

1.—The non-interchange of traffic between river and rail companies;
2.—Large terminal charges by some towns;
3.—Low railroad rates at competitive points; and
4.—Suspension of boat traffic by low water.

Another reason occurs to the writer: Many boat transportation companies have built up a considerable package traffic, with the almost unfailing result of having it destroyed by a second company entering the same trade and taking a large part of the first company's business, by cutting prices to such a rate as to destroy both companies. Until these wrongs are adjusted or remedied in some way, the river will continue to carry a diminutive package commerce and fail properly to serve the public or earn a fair value on the large expenditures for its improvement.

Unfortunately, neither the Engineer Department, nor other Government agency, manages or seriously concerns itself with any part of the transportation problem other than the preparation of a sufficient waterway. This question seems to be left mainly to the boatmen, members of Congress, and the annual two-day meeting of the several "Valley Improvement Associations". It is the writer's opinion that if the package-freight transportation rights of the river with its tributaries were awarded under proper and competitive methods to one reliable company, and operated under Government supervision, providing for efficient and reliable service at fair rates, the tonnage would be greatly increased. Should such a privilege for a long period be made to one of the largest and best railway companies crossing the river, thereby increasing its operating lines more than 3 000 miles, there is little doubt but that a great expansion in the tonnage would result. Such a policy, however, is in direct conflict with the popular policy of a free river and free commerce to every boat, which has been in effect since the formation of the Government; therefore, to effect the suggested change will require a struggle, like every other reform that brings great good. However, recent years of Government regulation of railway rates; of diminishing railway expansion and exploitation; of shrinkage in railway revenues and profits; and the more extensive realization by the public that the people along efficiently and reliably operated transportation lines profit many times more than the owners of the lines, will probably cause acquiescence to such a change much more readily than it would have done a few years ago. Since freight transportation by boat for short runs of less than about 500 miles, is cheaper and quicker than by railroad,

it follows as an incontrovertible conclusion that such transportation should be used and will be used when the right policy is evolved. Some Government agency should certainly be charged with the responsibility.

The capacity of the river for package and barge freight, when the improvement is completed, would easily be 25 000 000 tons annually and possibly double or treble that quantity. However, during the months the dams are up, the lockage capacity would be much below that rate.

Project for Improvement.—The appropriation by the Government for the improvement of the Ohio River for all purposes to June 30th, 1918, totals $59 500 000.

Since the design and construction of all the locks and dams on the upper half of the river, above the sill levels, are nearly the same, it is evident that the large differences in cost, as shown in the Annual Report of the Chief of Engineers for 1920, are largely due to the difference in the foundations. Other causes affecting such differences are prices of work as contracted, materials purchased, and management.

From 1890 to 1908, the policy was to construct first those dams below the large cities and below mouths of large navigable tributaries. This policy was modified later and now has become fixed in favoring a continuous order from the head of the river.

It is well known that a project substituting fixed dams for movable dams would be less expensive; but the requirements of navigation and the popular fear of an increase in flood heights made the building of fixed dams in this river appear at that time to be impracticable.

The project for the improvement as now contemplated was adopted by the Act of June 25th, 1910, per the report of the Lockwood Board.* The total number of locks proposed was 54, but by the Act of August 8th, 1917, it was proposed to construct one lock and fixed dam with high lift to replace Dams Nos. 1 and 2, and by the Act of September 12th, 1913, Dam No. 42 was omitted by increasing the lifts of several others, Nos. 43 to 46, inclusive.† It is proposed to omit Dam No. 40 by the increased height made in Dam No. 41. Before the system is completed, other modifications may make further reduction in the number; the omission of Dams Nos. 51 to 54, inclusive, now appears to be quite probable.

In 1894, there were in operation Lock and Dam No. 1 near Pittsburgh and Dam No. 41 at Louisville, Ky. In 1912, there were 13 locks in operation and in March, 1921, 33 locks had been completed, making a total of 432 miles of improved river.

Principal Features.—The principal features of a complete lock and movable dam with equipment, as constructed on the Ohio River, are the lock, navigable pass, weir, abutment and its bank protection, upper and lower guide-walls of the lock, lock esplanade and esplanade slope, bank protection below and above esplanade, power house, operating machinery, maneuvering boat and appliances, men's quarters and grounds, and fuel for power, heat, and light. Besides these auxiliaries, other important features to be arranged for or to be provided

* House Doc. No. 492, 60th Cong., 1st Sess., and additional information in House Doc No. 1159, 62d Cong., 3d Sess.

† House Doc. No. 1695, 64th Cong., 2d Sess.

are a turbine with complete auxiliary power machinery which replaces steam or natural gas engines when the dam is up, telegraph, telephone, mail service, highway and rail connections, farm lands, schools, churches, and amusements.

The original provisions called for a minimum navigable depth of 6 ft., a minimum width of navigation channel of 600 ft., and lock chambers 110 ft. wide by 600 ft. long between gates. The River and Harbor Act of March 2d, 1907, provided for an increase of navigable depth to 9 ft., and for moving the existing and prospective traffic, lock chambers 110 ft. wide by 600 ft. long between gates and navigable channels from 600 to 700 ft. wide, have become standard.

With the foregoing remarks on transportation conditions and on the plans and projects for improvement, a discussion of the principles influencing the location and design, together with some notes on construction and operation, with reference to Ohio River Dam No. 18, will be given.

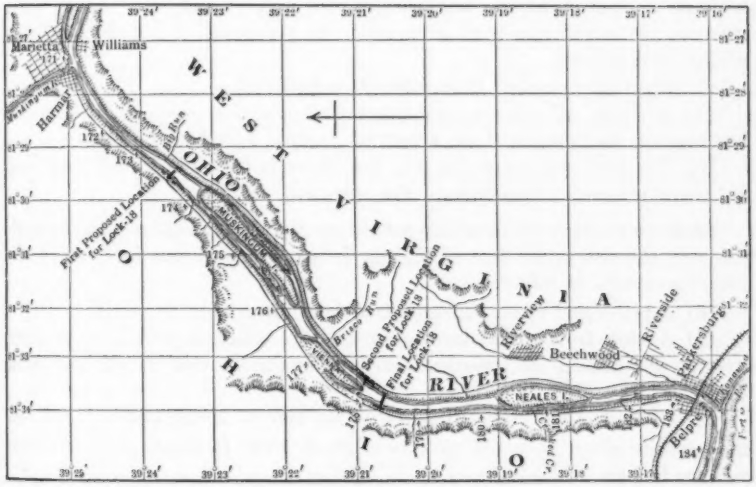

FIG. 2.

OHIO RIVER DAM NO. 18.

Location.—When the construction of Dam No. 18 was assigned to the writer in August, 1901, its proposed location had been changed from Moore Junction to the foot of Vienna Island (Fig. 2). Core drill borings over the Vienna site and the site finally chosen indicated that at the latter location was the highest ledge between the mouth of the Muskingum and the mouth of the Little Kanawha, the extreme limits for the location.

The final location having been decided on, surveys were made at the site chosen for the purpose of preparing estimates and plans. Topography on a 2-ft. contour interval was taken over the site, together with soundings taken

20 ft. apart over the areas covered by the proposed works and 40 ft. apart elsewhere.

Core drill borings were made on the center line of the upper and lower guide-walls, the center lines of the river and land-walls of the lock, the center line of the abutment, one hole at each gate recess, and two lines of holes, one above and the other below the proposed crest of the dam. The drilling was done from an open barge, 14 ft. wide and 23 ft. long by 3 ft. deep, with the floor a few inches from the keel, equipped with a machine drill operated by a gasoline engine.

It will be observed that the lock at Dam No. 18 is located on the concave shore. The principal reasons for placing it on the concave rather than on the convex shore are, as follows:

(1) The depth of water across the river admitted placing the sills at the height desired.

(2) It is on the extreme end of a bar with deep water immediately below, with no danger of having any part of the wickets and sill "sanded up"; whereas, the Island site is on a bar with the possibility of "sanding up" the wickets and pass sill.

(3) A saving in cost of from $200 000 to $400 000.

(4) As built, all the masonry has rock foundation, whereas, if the lock had been on the opposite shore, a part of it would have been on piles.

(5) The lock and approaches are less likely to "sand up", and, therefore, are less expensive in maintenance and operation.

Aside from the more favorable conditions for the foundations, in comparison with the site at the foot of Vienna Island, other reasons in favor of the site chosen are, as follows:

(6) A better and easier approach from both directions.

(7) A view from a distance up stream of 4 miles, and of 2 miles down stream, whereas, on the opposite shore, the up-stream view would have been ½ mile or less.

(8) Ground above high water lies within 200 ft. of the lock, whereas, on the opposite shore, it would have been about 1 000 ft. away, a great disadvantage in time of floods.

(9) A better location for the power house and dwellings which are above high water and near the lock and power house.

(10) It is 5 miles above the business part of Parkersburg, W. Va., and the mouth of the Little Kanawha River, at the upper end of the plateau on which Parkersburg is being built, which makes its location such as to be assured that, in years of future growth, that city's harbor will not be cut in two; and it is 7 miles below Marietta, Ohio, and the mouth of the Muskingum River, which is a favorable distance as to pool height and pool fluctuations for the mouth of the Muskingum and the wharf and harbor of the town. It is also so favorably located in reference to Parkersburg as to have city telephone service, city natural gas for heat, light, and power, and interurban trolley car service.

(11) The topography of the lock grounds is more adaptable to a pleasing appearance.

(12) The railroad spur to the power house is much shorter and less expensive to operate.

(13) It is near enough to the Muskingum River to give sufficient depth on the lower gate-sill of Lock No. 1 of that river, and yet far enough removed to reduce the annoyance and danger from drift, which would have existed had it been within 2 miles of the mouth of that river.

(14) Its distance from the mouths of the Little Kanawha and the Muskingum Rivers renders the annoyance from the maneuvers of the dam less than would occur to either if it was closer.

Design.—A theoretical detailed computation and design* for the following parts of a set of plans of a typical Ohio River lock and dam, as reported in 1912, by Capt., now Maj., L. M. Adams, Corps of Engineers, U. S. A., M. Am. Soc. C. E., have been made: Rolling gates; lock walls; gate track foundations; river wall power house; steam and water power plants; valve operating mechanism; gate operating machinery; analysis of design of wicket, horse, and prop; pile, arched cellular, and solid concrete pass foundation; and 91-ft. bear-trap weir and foundations.

In general, these parts are common to all locks and dams, except those which have mitered gates and those which do not have river wall power houses.

This information is a part of a public document and for that reason will not be repeated in this paper. However, the considerations and methods used in the determination of the dimensions of the various parts of the dam will be taken up in detail.

In regard to the movable parts of the dam, the writer reported to the District Officer, Maj., now Col., G. A. Zinn, Corps of Engineers, U. S. A., in part, as follows:

"In studying this design careful consideration has been given the designs of the Upper Ohio River dams, the Great Kanawha dams, and the Louisa Dam on the Big Sandy. You have already approved of the height of the sill for the pass, and of building the pass 600 ft. long of Chanoine wickets on a concrete foundation. It is therefore necessary now to discuss only the design of the weir and abutment."

In designing the weir, conditions of first importance to be fulfilled, as reported by the writer, were as follows:

1.—To regulate perfectly the height of the water in the upper pool, at all stages of the river at which it may be desirable to keep up the pass. In this case, it does not seem that it will ever be necessary to keep the pass wickets up when the river is above a 10-ft. stage.

2.—To place the weir sill so low that when the pass wickets are down, no boat or fleet will be stopped by the "swell head" or increased velocity of water through the pass.

3.—To make the dimensions of the weir, pass, and lock such that, with the lock-gates open and the dam down, the velocity of the water will not interfere with navigation. It is also desirable to have this condition fulfilled with the dam down and the lock-gates closed.

* House Doc. No. 1159, 62d Cong., 3d Sess.

4.—To place the weir sill sufficiently high to prevent its "sanding up". Ease of operation and regulation make it desirable to place the weir sill as high as possible.

5.—To arrange the weir for passing drift and floating ice with the least danger to the structure and the greatest ease to the operatives.

6.—It is desirable to place the sills of a bear-trap or other gate maneuvered by power, and a part of the weir sill adjacent to the pass, so low that when the pass wickets are raised at a stage below the top of the main weir sill, head cannot be produced sufficient to interfere with the raising of the pass.

7.—To have the dam of such a type that during the stages of least flow it will conserve sufficient water to maintain a full pool and also afford water for lockages.

8.—To have movable parts of the type which can be maneuvered with safety and ease.

9.—To adopt a type of dam which is the most economical in cost and in maintenance.

The Chanoine wickets and bear-traps appear, from the writer's observations on the Upper Ohio River, at Louisville, on the Great Kanawha, and from descriptions of European dams, to fulfill Conditions 5, 8, and 9 better than any of the other well known types of movable dams.

In regard to Condition 6, provision may be made against such difficulty by placing a 50-ft. bear-trap dam next to and at the same level as the pass sill. In his "Canalization de la Meuse", M. Hans says that the head referred to should not exceed 1 m. The writer believes that it is desirable to prevent its exceeding 1 or 2 ft. In the dams now being built, this condition is fulfilled by placing the sill of both traps at the same level as the pass sill.

Considering the question of tightness, Condition 7, it is believed that bear-trap dams can be made as tight as any other type of dam. Needles, curtains, gates, and, possibly, other types can be made tighter than wickets. With the use of wickets, calculations should show a shortage of water not more than once in 10 to 20 years. The lowest recorded discharge measurement of the Ohio River was taken in 1892, below the mouth of the Muskingum, the discharge being 3 255 cu. ft. per sec. Since this quantity is five or six times as much water as will be required for lockages, it appears that, with cover strips between wickets, sufficient water may be expected nine years out of ten, unless an artificial shortage is produced by the raising of dams up stream. Computations indicate that, with pass wickets 15 ft. high, with weir wickets, 12 ft. high, and with the pass and weir of the lengths proposed, the leakage through the interstices between the wickets will about equal the discharge of the river at a 3-ft. stage. Therefore, during several weeks of each year, needles over the interstices will be necessary.

Considering Condition 5 in reference to the passing of drift, it is found that below about a 9-ft. stage, with no wind, the drift is distributed almost uniformly over the surface of the river. As the water rises above a 9-ft. stage, with no wind, the drift goes to the Ohio or lock shore. The prevailing wind is from the west, and winds of 15 or 20 miles per hour cause nearly all the drift or floating ice to be driven against the West Virginia or abutment shore.

When the bear-traps can be maneuvered readily, they afford as easy a passage for drift and ice as any other well tried type of dam, and a safer one. As their cost and likelihood of getting out of working order increases rapidly with their length, two 50-ft. sections for passing drift were proposed, one in the middle of the river, for use when no wind is blowing, and the other next the West Virginia shore, for use when the wind is carrying drift and ice against that shore.

Conditions 1 to 4 will be considered jointly: At the site chosen there is sufficient room, without widening the river, for 500 ft. of weir, and computations were based on utilizing that width. In making the necessary computations for Condition 1, the most applicable formula is the Chanoine formula used for a similar computation in connection with the Louisa Dam on the Big Sandy,*

$$Q = m\,(L'\,H')\,\sqrt{2\,g\,(h + Z)} \qquad (1)$$

in which,

Q = discharge of river, in cubic feet per second;
m = constant depending on stage;
L' = length of weir;
H' = height of water on crest of dam above sill of weir;
g = acceleration due to gravity = 32.2;
h = height of water, or head, causing velocity of approach of water $= \frac{v^2}{2\,g}$; and,
Z = head due to swell caused by the water being forced through a reduced area on account of the construction of the works.

The values for m in Equation (1) and the following equations were selected from M. Hans' book, "Canalisation de la Meuse," in which all calculations were based on $Z = 0.5$ ft. After the completion of the Louisa Dam the late Mr. Thomas found the value of Z to be about 0.35 ft. when the lock-gates were closed. Therefore, the latter value of Z was adopted, and the correct value of m for the weir for various stages of the river was found, as follows:

0.5-ft. stage, $m = 0.458$
5.0-ft. stage, $m = 0.808$
6.0-ft. stage, $m = 0.811$
7.0-ft. stage, $m = 0.830$
13.0-ft. stage, $m = 0.896$

To determine whether the weir will regulate the upper pool when the water is at a 10-ft. stage, with the top of the weir sill 3 ft. above the top of the pass sill, apply the following values in Equation (1), $m = 0.885$; $L' = 500$ ft.; $H' = 12$ ft.; $h = 0.137$; $Z = 1.7$, the "swell head;" and $Q = 57\,700$ cu. ft. per sec. The discharge of the river at that stage is only 54 600 cu. ft., as shown in Table 3, which gives the discharge, area of section, velocity of flow, and velocity head for the Ohio River at Dam No. 18. Therefore, it appears that with the sill of the weir 3 ft. above the pass sill, the river can be regulated to a discharge equal to a 10-ft. stage, without any spill over the crest of the dam.

* "Movable Dams", by the late B. F. Thomas, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. XXXIX (1898), p. 469; or "Improvement of Rivers", by Thomas and Watt, p. 214.

The values of m and Z are only approximate. The value of Z may be considerably in error, but it is conservatively small for such conditions.

TABLE 3.

Gauge.	Quantity, in second-feet.	Area, in square feet.	Velocity, in feet per second.	Velocity head.
0	900	5 210	0.17	.....
1	2 940	6 380	0.46	0.003
2	5 550	7 530	0.74	0.008
3	8 910	8 620	1.03	0.0165
4	13 350	9 940	1.34	0.028
5	19 110	11 030	1.73	0.046
6	26 100	12 310	2.12	0.07
7	33 390	14 420	2.34	0.085
8	40 200	15 820	2.57	0.103
9	47 100	16 920	2.78	0.120
10	54 600	18 350	2.97	0.137
11	66 400	20 540	3.18	0.157
12	73 500	21 810	3.40	0.180

In making the computations for Condition 2, Equation (2) is applied:

$$Q = m\,(L\,H)\,\sqrt{2\,g\,(Z + h)} \qquad (2)$$

in which,

L = length of pass;
H = height of water on crest of dam above the sill of pass; and
Z = swell head.

In these computations a "swell head" of 0.25 ft. is assumed. The problem to be solved in this case is, how high can the weir sill be placed without the "swell head" through the pass exceeding 0.25 ft. Assume that the water is at a 3-ft. stage, or 4.6 ft. above the pass sill, and that the weir is closed. It is found that there can be discharged through the pass, with a "swell head" not exceeding 0.25 ft., 9 186 cu. ft. per sec., whereas at that stage the actual discharge, as shown in Table 3, is 8 910 cu. ft. per sec. Therefore, with the weir sill not more than 4.6 ft. above the pass sill, the "swell head" should never exceed 0.25 ft.

It is found in meeting Condition 3 that if this condition is fulfilled with the water just to the top of the lock river wall (or 16.4 ft. stage) and with the lock-gates closed, it will be fulfilled under all other conditions which are likely to arise. In making this computation, the formula of Chanoine and De Lagrene, used by Maj. Lockwood and the late Mr. Thomas,* for a similar computation for the Louisa Dam, namely,

$$Z = m\,v^2 \left(\frac{S^2}{S_1^{\,2}} - 1\right) \frac{1}{2\,g} \qquad (3)$$

in which,

Z = "swell head," in this case, 0.25 ft.;
v = mean velocity;
S = discharge area of river before construction of works;
S_1 = discharge area of river after construction of works; and
g = 32.2.

* *Transactions*, Am. Soc. C. E., Vol. XXXIX (1898), p. 471.

Substituting the proper values in Equation (3), in which $Z = 0.25$; $m = 1.05$ instead of 1.5 when the "swell head" is reduced from 0.5 to 0.25; $v = 4.34$; $S = 24\,600$ sq. ft.; and $S_1 = 18\,250$ sq. ft.

Using 135 sq. ft. as the discharge area over the top of the piers and abutment, to find the height of the weir sill to give the foregoing area, apply Equation (4):

$$135 + 500\,x + (600 \times 18.0) = 18\,250 \ldots\ldots\ldots\ldots\ldots\ldots (4)$$

Solving for x, the height of the weir opening = 14.63 ft. Therefore, 18.0 ft. — 14.63 ft. = 3.37 ft., the height the top of the weir sill may be above the pass sill and not cause a "swell head" exceeding 0.25 ft. Substituting the values of Z and h from Equation (4) in Equation (5):

$$V = \sqrt{2\,g\,(Z + H)} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (5)$$

the velocity of water through the pass at these critical stages is obtained. With the weir closed, and the water 3 ft. deep on the pass sill, the velocity is 2 miles per hour; and when the water is at the top of the river wall of the lock, with a weir sill 3 ft. above the pass sill, the velocity is 4 miles per hour. It is not believed that a velocity of less than 5 miles per hour will seriously interfere with fleets of empty barges going up stream. During construction, in 1908, such fleets passed between the lock and weir coffer-dam against a 7-mile current.

Relative to Condition 4, from experience at other dams, it is known that when the sill is placed too low, there is likely to be serious trouble from sanding.

After considering all these conditions and the development of the bear-trap at that time, the writer recommended that the weir be divided into three parts, as follows:

First.—Next the pass, a bear-trap dam, 50 ft. long.

Second.—Chanoine wicket, 400 ft. long, operated by a bridge.

Third.—Next the abutment, a bear-trap dam, 50 ft. long.

Also, that the sill of the bear-trap next to the pass be placed at the same level as the pass sill, and that the remainder of the weir sill be placed 3 ft. above the top of the pass sill, or 1.4 ft. above low water. These recommendations were adopted, except for the wicket weir which was made 300 ft. long and the pass, which was made 700 ft. long, as ordered by the Chief of Engineers. This resulted in easier and possibly safer navigation for some fleets of boats, but more difficult operation, and, in case of a rapid rise, an increase in the hazard.

In the report of the Lockwood Board* is a diagram of a large coal tow for the upper river. This tow is 130 ft. wide by 696 ft. long. There is also a diagram of one of the largest fleets on the river below Louisville, 312 ft. wide by 1132 ft. long. It is thus evident that in order to operate with ease and efficiency a series of movable dams, the navigation passes must increase in length as the river increases in width. As the weir of Dam No. 18 was designed before any of the others between it and Dam No. 6, its length could not be governed by the lengths of any weirs on the river, except those of Dams Nos. 1 to 6. If designed in order, it is evident that each weir in succession down stream,

* House Doc. No. 492, 60th Cong., 1st Sess., v. 18.

should have the capacity of the one above when fully open, plus the tributaries emptying into its pool.

Wickets.—The location of the exact place for hinging the wickets was studied from both the theoretical and historical points of view, the design of the wickets for all other dams of which plans could be obtained, being considered.

The correct general principle for the hinging of the pass wicket may be briefly stated as follows: The axis of rotation for pass wickets should be placed as low as possible, but at such height that they will never automatically go on swing from head of water alone. Computations for Dam No. 18 indicate that the pass wickets will never go on swing without some force other than the water.

When operated by a bridge, the general principle for hinging the weir wickets may be briefly stated thus: The axis of rotation should be placed so that the wickets will automatically go on swing just at the time the lower pool rises to that height at which the dam should be lowered. In general, the wickets will not be depended on to work automatically, but are designed to work in this manner in case of emergency and for ease in operation. Should a rapid rise occur, and the attendants be slow, or should an unexpected rise occur at night and not be observed, the upper pool may be relieved by the automatic swinging of the weir wickets. Computations for the weir wickets of Dam No. 18 indicate that they will automatically swing at the time the upper pool level rises 6 in. over their tops and the lower pool level reaches a stage of about 9½ ft. above low water.

It would probably be better to hinge the weir wickets so that they would not swing with less than 1 ft. on the crest. However, there is not entire agreement on that rule. After years of operation, the writer believes the hinge point for the pass wickets is satisfactory. For the weir operated with a bridge, the percentage for butt might be slightly increased. For weirs operated with a boat, it is never desirable to have wickets hinged so as to swing automatically. If hinged to swing so easily, they might possibly fail to hold the maneuver boat at stages over the crest. On one occasion a rise with about 18 in. of water on the crest, head reduced to about 4 ft., and acres of heavy drift against the maneuver boat and dam, caused the pass wickets below the boat to swing, dropping the boat over them into the lower pool.

For this study, the writer had computations made which indicated that with very slow current, 6 in. on crest, and with the following height of heads to hinge the weir wickets so they would just swing, the percentage for breech should be as given in Table 4.

TABLE 4.

Head, in feet.	Length of breech, in feet.	Length of wickets, in feet.	Percentage of breech length.
8	5.28	12.92	41.
9	5.48	12.92	42.4.
10	5.71	12.92	44.2
11	5.95	12.92	46.

The designer must consider two forces, namely, the increased pressure against the butts by increased current, and the increased pressure at the top of the chase by increased pressure of the drift or of the maneuver boat. With these conditions known, and his method of operation determined, he is then prepared to determine his hinge point.

After the plans were prepared, the length of the pass and weir wickets and the relative length of the butt and chase were reported for each, as follows:

Pass wickets:

16 ft. $0\frac{1}{4}$ i . long.... { Breech, 8 ft. $2\frac{1}{4}$ in., 51.12% of length. Chase, 7 ft. 10 in.

Weir wickets:

12 ft. $11\frac{1}{16}$ in. long.. { Breech, 5 ft. $7\frac{9}{16}$ in., 43.5% of length. Chase, 7 ft. $3\frac{1}{2}$ in.

The wickets were of long-leaf yellow pine which the writer considers the best wood for the purpose, because it remains true to its original form. In many of the dams, white oak wickets have been used exclusively. The difference in their strength or life for use as a wicket are not material considerations.

The Bebout Wicket.—The only improvement of the Chanoine wicket, which has been used is the Bebout wicket. The first wicket of this type for practical use was installed in the pass of Dam No. 18 in 1914.

Fig. 3 is a view of Bebout and Chanoine wickets at their junction in Dam No. 22, and Bebout wicket horses assembled on their foundation.

The advantages claimed by the inventor for this wicket over the Chanoine are:

1.—It can be raised with ease and without loss of time at any open-river stage up to the top of the wicket.

2.—It can be raised against any differences in pool levels, if sufficient power is applied at the chains; it is possible to raise it against an 8-ft. difference in pool levels with comparative ease and without delay.

3.—It can be lowered under all conditions of river stages and pool levels.

4.—With adaptable appliances, the wicket may be maneuvered from either the upper or the lower pool.

5.—During maneuvers all parts have little exposure to drift, both floating and submerged, whereas Chanoine wickets have great exposure.

6.—When raising wickets, drift cannot, except in extreme cases, obstruct or become entangled in the parts to such extent as to prevent this maneuver.

7.—The sill and foundation of the dam, and the wickets themselves may be completely covered with sand and gravel without serious delay to the maneuvering.

8.—A boat, barge, or heavy drift in striking the top of the wicket will cause it to collapse without damage to boat or dam.

9.—In case of a sudden rise overtopping the wicket, it will either trip or else form no obstruction to navigation.

10.—It is impossible to have the dam caught by a sudden rise in the river, and not be able to lower the wicket.

11.—The sill and foundation of the dam can be washed by raising the butts of the wickets in the same manner as with Chanoine wickets.

12.—The maneuvers are direct and are made in one operation. Raising and lowering may be accomplished in a short time.

13.—The first cost of wickets and foundation should be no greater than that of Chanoine wickets.

14.—For the same factor of safety, the foundation will be materially cheaper; or, for the same foundation, the factor of safety will be greater.

15.—The maneuvers may be performed from the lower pool in case of emergency.

16.—Less equipment and no powerful sinking device is required to sink the wickets.

17.—The ease with which wickets may be maneuvered should reduce the operating costs. There is less wear and tear on the operation of the appliances, wickets, and foundation.

18.—Nine or ten men should be able to operate a lock and dam instead of thirteen or eighteen, as may be required to operate dams with Chanoine wickets.

19.—Since the dam may be raised at any stage of the river, it is unnecessary to allow the lower pool to drop below normal and a 9-ft. stage will be provided without interruption.

20.—Complaints from boating interests will be reduced to a minimum, since no boat should be stranded when dams are raised.

21.—A saving will be effected by the avoidance of a large number of long-distance telephone calls. It will not be necessary to telephone except to give notice of the approach of quick rises. Each lock-master to a great extent can operate his dam independently of other dams.

22.—The wicket is well adapted for use as an emergency gate and could be used as such during the renewal or failure of a lock-gate, and could be made to serve the purpose of a coffer-dam during repairs to locks.

23.—It is possible to dispense with one bear-trap and all the present weirs at the upper river dams, replacing them with a navigable pass-section equipped with the new wickets.

24.—Both the bear-traps and the Chanoine weir could be dispensed with at the lower river dams.

Since the Bebout wickets are maneuvered successfully against heads of 10 ft., or more, a cluster of two or three for passing drift near each end of the pass is such a great convenience, that two or more clusters may eventually be considered essential in the passes of all the dams.

Bear-Traps.—In 1904, when the writer was preparing the plans for the bear-traps for Dam No. 18, the principal traps then known to him were the wooden ones in Dams Nos. 1 and 6, designed in 1898 and 1900, the two steel traps in Herrs' Island Dam, Allegheny River, the three-leaf dam in the Louisville Chute, and the wooden three-leaf dam in the Mississippi River at St. Paul, Minn. All these dams were in service except Dam No. 6, and the engineers directly in charge were believed to consider each suitable for its purpose.

After discussing the merits of each with the District Officer, and after a study of the best papers he could find on the subject, the writer recommended

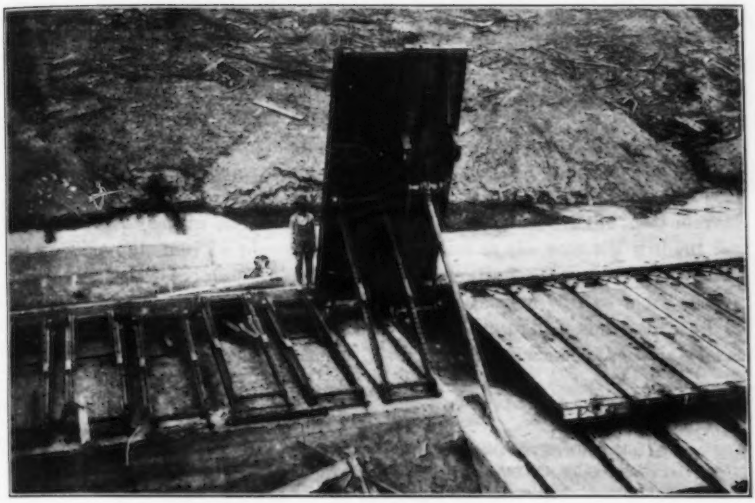

FIG. 3.—BEBOUT AND CHANOINE WICKETS AT THEIR JUNCTION IN OHIO RIVER DAM NO. 22, AND BEBOUT WICKET HORSES ASSEMBLED AT THEIR FOUNDATIONS.

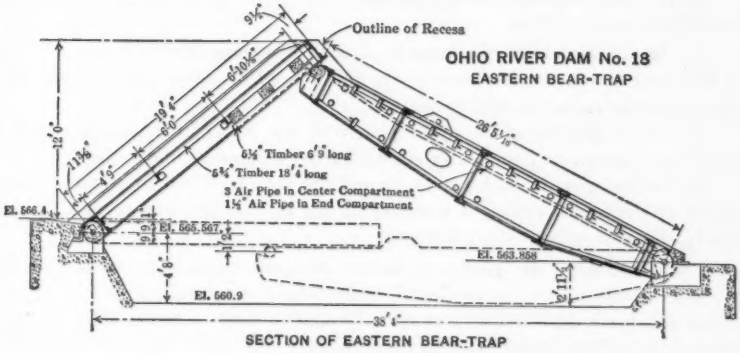

FIG. 4.—VIEW OF COMPLETED WEIR, DAM NO. 18.

steel traps for Dam No. 18, and with the aid of the Junior Engineer, the late C. J. Rannells, Assoc. M. Am. Soc. C. E., prepared the designs and working plans for two 50-ft. traps. Fig. 5 is a cross-section of the eastern or smaller bear-trap.

The traps were completed in 1908 and put in operation in May, 1910, and have always maneuvered with ease, under any conditions of river.

The years of experience with these traps, and the many other traps since constructed for other dams, has demonstrated that for regulating the stage of water in the pools, for ease of operation, and for safety of parts, the bear-traps, in 50-ft. lengths and as since built in 91-ft. lengths, are the ideal movable parts. The sills may be placed at the same level as the pass sill without fear of "sanding up" seriously interfering with operation.

It is believed that the maneuvers of the entire dam will be more efficient and made much easier by placing both traps next to the abutment and the wicket weir next to the pass wickets. With this arrangement, the weir wickets

SECTION OF EASTERN BEAR-TRAP

FIG. 5.

and the pass wickets can be operated by the same maneuver boat, thereby eliminating the bridge which is much more difficult to maneuver and to keep clean of drift than the wickets alone. Therefore, the writer would recommend placing both bear-traps next to the abutment, the 400-ft. wicket weir, with 11-ft. wickets, between the traps and the pass, and making the bank protection below the abutment sufficient to withstand the increased scour.

Care was used in the design to obtain the greatest possible head for acting on the leaves. The girts were made stiff enough to lift the dam with air under only one-third, or one compartment, of the lower leaf, or stiff enough to admit of a deflection of not more than 1 in. when lifted with water alone, the water entering from one pier only and giving a maximum pressure at one end and zero at the other. It was believed that the great deflection under such conditions was the most serious defect in traps previously constructed. The galvanizing of the thin parts of metal and the use of nickel steel were considered; but plain carbon steel was used throughout on account of the cost and the difficulty in galvanizing such large sheets as those used on the skin.

For convenience in cleaning, repainting, or in making repairs, manholes were placed in the lower leaf and in the girts. Wooden water seals were used for closing the gap between the leaves and the masonry. When the central trap was cleaned in 1914, the seals were found to be entirely destroyed, and new ones were not considered essential, since no difficulty had been experienced in operation. In the later designs, metal seals are being installed.

The dimensions of the leaves were as follows:

Westerly, or larger bear-trap:

Length of lower leaf, 34 ft. $0\frac{3}{16}$ in.
Length of upper leaf, 24 ft. $4\frac{3}{16}$ in.

Easterly, or smaller bear-trap:

Length of lower leaf, 26 ft. $10\frac{1}{16}$ in.
Length of upper leaf, 19 ft. 4 in.

All the dimensions are given from center of hinge to extreme end.

Ordinarily, the most severe stresses will occur under the following three conditions of operation:

1.—In the girders of the lower leaf, with low water in the lower pool, and a full pool above, the trap partly up, and a head of water applied with sufficient force to raise the trap to the top.

2.—In the girders of the upper leaf, with low water in the lower pool, and a full pool above, and the water emptied from the recess under the trap.

3.—In the girts of both leaves, should the trap be lifted by water pressure alone, applied with sufficient pressure at one end of the trap to move it and diminishing to zero at the other end.

Computations were made to insure strength enough to withstand the stresses which might be produced under other assumptions not so severe. Since the lower leaf is likely to be subjected to more severe conditions than the upper leaf, the same working stresses were not used. The working stress used in the girders of the lower leaf was 6 200 lb. per sq. in., and in girts 8 000 lb. per sq. in. The estimated cost of the movable part of the eastern trap, 12 ft. high, was $148.38 per lin. ft., and that of the western trap, 15 ft. high, $212.28 per lin. ft. From 1 to 1½ min. are required to raise the bear-traps at any stage with 18 in. of head or more, and they may be lowered at any stage within 1 min. They maneuver with either water or air, or both. Ordinarily, only the water pressure is used.

The widths of the piers from which they were operated and supplied with water are 11 and 12½ ft., respectively. The hydraulic head has always been sufficient to operate the traps when the wickets are up. In submitting the plan for the traps to the District Office, the writer stated, "it appears that, if the mechanical working of the traps now in service was perfect, it would be better to make the traps longer than 50 ft. When the working of the traps has been made perfect, the economical length of any series of traps will depend largely on the character of the foundation, but such lengths will generally fall between 75 and 150 ft." (See page 129.) The standard length for the Ohio River bear-traps is now 91 ft. in most of the dams, and they

are placed between the pass and wicket weir. They are now built and operated with the same confidence of success as lock-gates or other similar structures.

Plan for Lock.—In 1902, when the plans and specifications for Lock No. 18 were submitted to the District Officer, Locks Nos. 1 and 6 had been completed and Nos. 2 to 5, inclusive, were under construction. The plans for Lock No. 18 included the following details which differed from the dams previously mentioned:

1.—Masonry all monolithic Portland cement concrete, instead of cut stone as used in Locks Nos. 1 and 6; or of natural cement faced with Portland cement, or with timber on the chamber walls and coped with stone like Locks Nos. 2 and 5 then being built.

2.—Faces of chamber walls and guide-walls battered ¾ in. in 12 in. instead of being vertical.

3.—The top width of river wall along the chamber, 8 ft. instead of 11 ft.

4.—The flushing of conduits and drift chutes omitted and, instead, each gate recess provided with stop planks and sump for use in annual unwatering and cleaning.

5.—Gate and valve machinery operated by fluid or air machinery instead of steam.

6.—Ten emptying and filling valves instead of sixteen, but with equal capacity.

7.—Each valve operated by its separate engine instead of all being operated by one engine.

8.—Valves rectangular instead of circular.

9.—The pipe well and conduit omitted and, instead, the pipes laid across the lock, descending and ascending the lock walls in open channels in the concrete.

All these features were approved except the battering of the chamber walls and the form of the valves, and, except for the number of valves, have become standard construction on Ohio River dams. Rectangular valves have since been introduced. All engineers in charge of the operation of locks with battered walls, who have expressed their opinions to the writer, prefer the battered rather than the vertical walls. The battered face is not cut so rapidly by the rubbing of boats; it also enables boatmen to walk the gunwales of barges when moored in the lock and, for an equal area of section, it gives a slightly increased factor of stability. The fact, however, that the lock walls when completed were of the vertical type was good reason for not making the change. All the lock masonry is designed for stability as gravity walls; the river wall on the assumption of being completely unwatered and with a stage of the river to the top of the wall; the gate tracks and Poirée dam foundations on a similar hypothesis, and the land wall and guide-walls on the hypothesis of being surcharged retaining walls. They were not designed on the hypothesis of having a full head of water under the entire foundation masonry beds, but it was considered that such a head might occur over small areas of the foundation. Thinner walls of reinforced concrete were considered for the guide-walls, but were discarded on account of the danger from shock by heavy boats or by fleets of loaded barges.

Construction Features of Dam No. 18

Plant and Materials.—In building Lock No. 18, the sand and gravel required for the concrete was taken from the river bed near the site. Coal was obtained by barge from river mines, and nearly all the remaining materials were received on a spur track of a railroad the line of which passed along the top of the bank within 50 ft. of the work. Materials were transferred to the work from storage sheds and yards along the siding by tramway cars operated by men and mules.

The contract for building the dam and abutment was let about a year before the lock was completed. The contractor received materials in the manner previously described, except that his coal and some other materials arriving by rail were received near the West Virginia river bank on a siding about 800 ft. from the abutment, and carted to the work by teams. Materials from the latter siding were transferred to the work by a cableway. The cable was maintained as required by law at a minimum height of 90 ft. above low-water datum. The towers were set well back from the bank, making a clear span of about 1 760 ft., thus securing protection against accident and giving adequate storage and loading space for materials and plant.

The best and most economical method of transfer to be adopted for building any particular lock and dam will be influenced by the economy of extending standard railroad track to the river bank alongside the work, or down into the lock coffer-dam. The use of a cableway is more expeditious than other methods.

It is conceded that every flood over a coffer-dam, when work is fully under way, will cost in actual damage and expense rarely less than $1 000 and usually much more. The cableway is especially advantageous and adaptable to this work, since the cost and time of transfer of the materials and plant from the coffer-dam in case of flood are greater by other methods. Whether or not its use is advisable, depends on the quantity of material which can be moved advantageously. In the writer's opinion, the sand and gravel required for the concrete can be unloaded more economically from the barges, by fixed or floating derricks, and it is more economical to move the concrete from the mixers to the forms by tramway, or by chutes, than to move it and place it by cableway. This economy is due to the fact that buckets from the cableway are not easily dumped in the forms. Also, the sand and gravel must be unloaded from barges moored under the cableway in the navigation channel, which is a dangerous process at stages below 6 ft., and impracticable at stages a little higher, thereby resulting in serious delays to concrete construction. The work advantageously done by a cableway and for which it is especially adapted is the transfer of all materials to their place in the coffer-dam enclosure, and the transfer of plant and tools to and from their place of usage.

Coffer-Dams.—The construction of the No. 18 lock, dam, and abutment required four coffer-dams: One for the lock, one for the abutment in which one section of bear-trap foundation was included, one for 650 ft. of the pass, and one for the weir, bear-traps, and the remaining 50 ft. of pass. For building the

guide-walls of the lock, levees 8 ft. in height were thrown up from material excavated in preparing the foundation.

The proper order for building the coffers is, first, the lock and abutment coffers; second, the pass coffer; and, third, the weir coffer. It is not important whether the lock coffer or the abutment coffer is started first, or whether both are started together. The other two, of course, must follow in succession; but it is important to have the masonry and the bank back of the masonry finished and sufficiently protected against scour, since the latter coffers produce a "swell head" and increased current.

Due to the high sill of the weir, it is essential to build the pass before the weir. On account of the "swell head" and high velocity of current, it is expensive, more or less dangerous, and detrimental to navigation to hold the weir and pass coffers in the river over winter.

The program followed by Government forces and by some contractors on lock and dam construction is to complete the work and remove the coffers in early winter. Some of the slower contractors increase the number of coffers to five, the fifth being made to enclose the bear-traps and adjacent end of the pass. It is unusual for the construction of the lock to be completed in one season; hence, it is customary for the lock coffer to be continued in service over one winter.

For the lock, a crib coffer was built, enclosing the entire lock and lock area as planned and specified by contract. The abutment and dam box coffers were specified with the option of changing, subject to approval by the contracting officer.

In studying the economical height of these coffers, the writer used the hydrograph sheets of daily stages at Marietta, and from them computed the probabilities of coffers varying in height from 10 to 20 ft. being flooded during the working season. With the adopted height of 18 ft., it was concluded that the work would probably be flooded once during the working season from May to December.

In constructing the lock coffer, a channel was dredged with a dipper-dredge, the bed-rock being scraped as clean as possible. The cribs were built in water and sunk on the rock ledge thus prepared. The logs forming the longitudinal walls were barked on the inside, and those forming ties were wrapped with several rings of oakum to retard seepage. To reduce leakage to a minimum all the wall cracks were carefully covered, and selected material was used for filling the pockets. This coffer-dam was built in the spring of 1903 and was in use until the fall of 1904, going through a winter and spring of much high water and a long run of ice from 12 to 18 in. thick. The resulting damage was repaired at a cost of less than $50. Two 12-in. centrifugal pumps easily kept out the leakage, and at stages up to within 2 ft. of the top of the coffer-dam, one pump removed all the leakage. The inside wall was vertical, and stood about 10 ft. from the concrete masonry. The top being so near the permanent work, proved a great convenience for storing materials and offered no obstruction to the transfer of materials from barges and other boats by derrick-boat into the concrete forms or to the top of the wall. This proved to be more economical than the box coffer, with its top 40

ft. or more from the masonry, which is a serious obstruction in the transfer of materials required in the work.

The coffer which enclosed about 600 ft. of the pass, was built in 1905 and was of the box type. It was 602 ft. long inside by 150 ft. wide at the river wall and 200 ft. wide at the outer end, and rested on bed-rock with the top 18 ft. above low water. The upper arm was 20 ft. high at the river wall and 32 ft. high at the outer or channel end. The contractor chose this type at his own option; whereas the writer believes that a crib coffer-dam of the type used for the lock would have been more economical for that part of the pass where the high elevation of bed-rock made necessary a coffer wall only 20 to 25 ft. in height. The pass coffer was poorly built and was wrecked when overtopped by a flood, as shown on Fig. 7. Presumably built to hold out water at 14 to 16-ft. stages, it was effective only to 12 ft., on account of leakage, at which stage three 12-in. pumps were required continuously.

Five separate attempts were made at levee and coffer building for the abutment. Work was first commenced in June, 1905, and continued through the seasons of 1905, 1906, and 1907. The abutment masonry, sheet-pile protection, and the bulkheads extending the seal into the bank behind the abutment, were not finished until November, 1907. The masonry plan showed the foundation bed 22 ft. below low-water level, and the contractor made two unsuccessful attempts to build the abutment within a simple levee made from the light bank material. The third attempt was a rather light box coffer-dam. The two levees and the light box were entirely swept away by the river before the concrete forms were built, and, later, a second box coffer was lost. The fifth and successful attempt followed the construction of a fairly substantial box coffer, protected with round piles and rip-rap.

The weir coffer for Dam No. 18, built by Government hired labor, was placed by having both lower and upper arms run out from shore simultaneously and connected by the channel arm. The timber and metal for the coffer was salvaged from the coffers which preceded it. The bed-rock was from 14 to 23 ft. below low-water datum. The bed on which the sheeting stood was prepared with dredges excavating or refilling as required to level it to 14 ft. below low water. The lumber for the coffer-dam was framed on shore and on a work barge, and erected in position alongside. The width of channel left for navigation between the coffer-dam and the river wall over the pass sill and wickets was 384 ft. and, in addition thereto, the lock chamber was open.

A report made in reference to the coffer-dam while the work was in progress is, in part, as follows:

> Size inside, 590 by 225 ft.
> Height of upper arm, 37.5 ft. at shore to 32.0 ft. at outer end.
> Length of upper arm, 590 ft.
> Pumps required at 12-ft. stage of water, four 12-in. centrifugal.
> Extreme lift by suction, 17.0 ft. } = 38 ft. total lift.
> Extreme lift by discharge, 21.0 ft. }

The difference in the efficiency of the three coffers in holding out the water was so great that it is worthy of note:

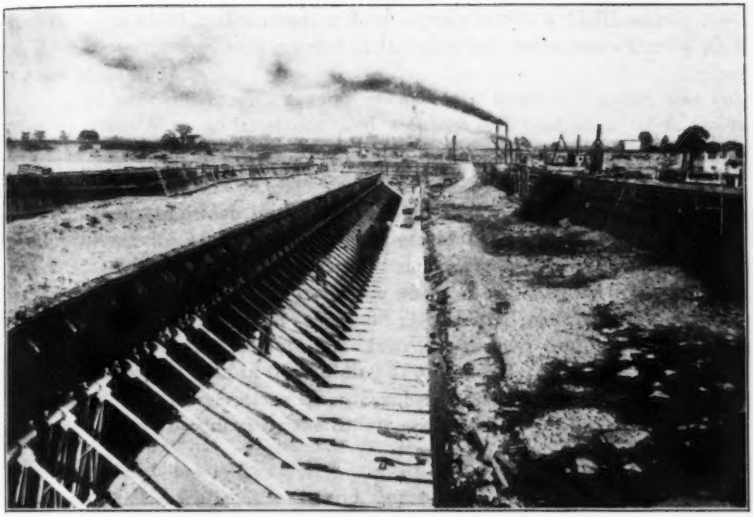

FIG. 6.—VIEW OF PASS MASONRY, DAM NO. 18, OHIO RIVER.

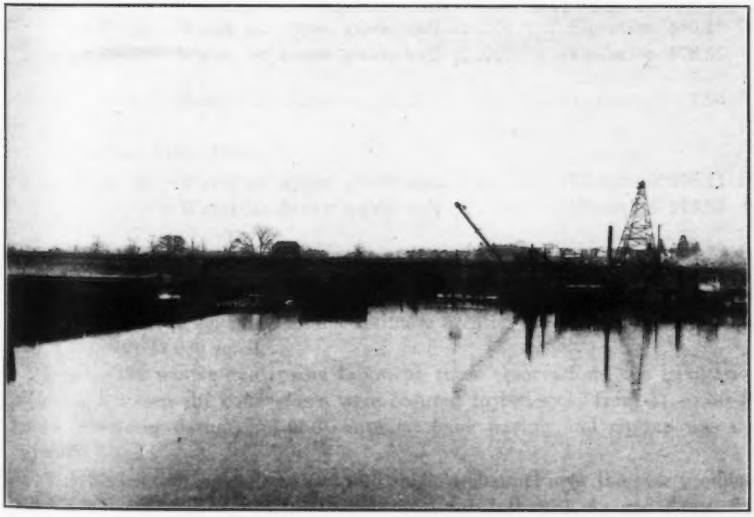

FIG. 7.—DAM NO. 18, OHIO RIVER: VIEW OF COFFER-DAMS AFTER 8-DAY FLOOD, NOVEMBER 30–DECEMBER 10, 1905.

1.—The crib lock coffer set on bed-rock was effective and the work of construction was continued through a flood slightly above a 16-ft. stage.

2.—The weir coffer, with a sump 23 ft. below low water, was effective up to a stage of 12 to 14 ft.

3.—The pass coffer, with a sump about 14 ft. below low water, was only effective from 8 to 10-ft. stages, and actually collapsed at a 9.5-ft. stage, wrecking all the plant inside. Such differences in the efficiency of the coffers had great effect on progress and on the cost of the permanent work.

Two things of great importance in building a coffer-dam are, first, to obtain the service of a designing engineer of experience to select the type best adapted for the particular purpose and duty; and, second, to engage on its construction a foreman or mechanic who can be relied on to close cracks, wrap tie timbers or rods, and select and place filling material so as to reduce the percolation to a minimum. In few construction details does vigilance pay greater returns than in the building of a deep coffer-dam.

Swell Head.—Observations taken October 23d and 24th, 1905, to determine the "swell head" produced by the coffers are, as follows:

October 23d, 1905:

10 A. M.—Water at lower end, upper guide-wall...Elevation 580.89 ft.
Water at lower end, lower guide-wall...Elevation 579.01 "

Head ..... 1.88 ft.

Stage about level with top of 16-ft. coffer-dam and falling.

5 P. M.—Water at upper guide-wall.....Elevation 580.18 ft.
Water at lower guide-wall.....Elevation 578.55 "

Head ..... 1.63 ft.

October 24th, 1905:

9 A. M.—Water at upper guide-wall.....Elevation 578.11 ft.
Water at lower guide-wall.....Elevation 576.89 "

Head ..... 1.22 ft.

The normal regimen of the river at a 16.0-ft. stage before work was commenced was 24 000 sq. ft. The approximate area of the openings, on October 23d, 1905, was 11 080 sq. ft.

During the winter and spring following these observations, the navigation channels between the coffer-dams were scoured to bed-rock, from 17 to 20 ft. below low-water datum, but the abutment bank paving and rip-rap was not injured.

This restriction in such a short and shallow channel over the pass produces the swiftest current caused in the construction of these locks and dams, and is near the maximum which Ohio River boats find tolerable. Under such conditions at Dam No. 33, ascending packets and gasoline boats sometimes used lines to pass the dam and occasionally turned back; towboats cut their

tows in two or more parts during the two winters this condition existed. Under all conditions and positions of the coffer-dams, the maximum "swell head" and swiftest current usually occur at a stage which is about the top of the obstruction and is generally greater on a rising than on a falling river.

Masonry.—Fig. 4 is a view of the completed weir. Fig. 6 is a view of the pass masonry. The 200 lin. ft. in the foreground varies in thickness from 12 to 36 in., the thinnest wicket foundation masonry on the river. The wickets that it carries, have been in successful operation since 1910, which demonstrates the great economy of a rock foundation near the sill level and, also, that a very thin concrete slab well anchored to the ledge is sufficient.

For the pass, it was computed that under extreme conditions there might possibly be an upward pressure of $53 000 lb. against a single wicket foundation slab, 4 ft. in width. The concrete foundation for the pass is 27 ft. wide by 700 ft. long and varies from about 12 in. in thickness at thinnest part of the slab to 15 ft.

Two plans were considered for anchorage, one of which required four 2½-in. bolts for each 4 ft. of the slab, two in the upper edge and two in the lower, with the intervening concrete reinforced with steel rods. The other plan required two 2½-in. and six 1-in. hurter bolts into bed-rock for each 4 ft. of slab, or, in other words, for each wicket. The latter plan was finally approved, except that only two of the 1-in. hurter bolts were authorized to be made for anchors into the bed-rock. Therefore, as built, where the concrete is less than about 6 ft. thick, it is anchored to the bed-rock with four bolts for each wicket, two of which are 2½ in. in diameter and two 1 in. in diameter. The 2½-in. bolts were placed about 4 ft. into bed-rock and the 1-in. bolts about 3 ft. therein. The anchor-bolts for the bear-traps are 2¼ in. in diameter and are placed 4 ft. into bed-rock. When the grout around one of the 2½-in. bolts which went into the bed-rock only 42 in., had stood for less than a day, it failed to move by a lift of more than 20 tons, the greatest pull for which facilities were available.

In laying the foundation, great care was used to make an impervious joint to the bed-rock foundation for the upper third of its entire surface. In other words, the seal between the upper and lower pools was made along and immediately below the upper face of the dam. To make this seal as perfect as possible, all loose shale was removed, and the bed-rock was scrubbed with brooms and water. Thus prepared, fresh mortar was spread over the foundation bed, followed by concrete. In placing the foundation layer, care was used to see positively that no stream of water crossed it, and that any stream which came up through a crevice in the bed-rock was conducted out below the dam without producing any head or upward pressure. Under the lower two-thirds of the foundation, drains were inserted at intervals of about 20 ft. to carry off any water which might seep in. All concrete up to the top of the rock was placed without forms, thus securing bond into all the interstices of the ledge.

The foundation for the chamber walls of Lock No. 18 was prepared by excavating to a depth of 1 ft. below the chamber-floor level, carefully removing all loose rock and cleaning with hose and brooms. Immediately on top of

the ledge thus prepared and drained, grout was spread, in order to make as nearly as possible an impervious joint between the concrete wall and the bedrock. For some locks on the river, a key about 2 ft. by 2 ft. was cut into the rock along the center line of the lock walls.

The superior quality of the structures with the masonry laid on rock ledge over those laid on piles appears to the writer a more important reason for seeking a location with rock foundation and for holding to it when found, than even great differences in cost.

Most of the old cut-stone locks and dams built from 25 to 75 years ago show serious signs of failure. It is entirely possible that most of the locks and dams being built in the Ohio River will be satisfactory for the purpose intended, without change in design, for 100 years or more. Therefore, it appears desirable to take every reasonable precaution to obtain excellency of work.

For that part of the pass foundation of Dam No. 18, which is more than 8 ft. deep, and for all the wicket weir foundation, a plan was prepared for the cellular type, but the bid for the solid type proved to be the more economical. For the bear-traps only the cellular type was planned. In placing the cellular masonry for the bear-traps, drains were used to relieve any head which might otherwise occur. However, entire dependence was not placed on such expedients, but the cellular bear-trap masonry was bolted to the ledge with 2½-in. bolts. There were some indications of the passage of water through the bedrock, principally in the sandstone where anchor holes were drilled, water spurting 3 or 4 ft. from several of the anchor holes for the westerly bear-trap. It was the usual custom to place all the masonry in monoliths about 30 to 35 ft. long, the full width of the wall. In placing the monoliths, the rule was to key alternating sections with from one to three vertical keys about 2 ft. wide and from 6 to 20 in. deep, at intervals of not more than 8 ft., and not more than 6 ft. from the outside surface of the wall. Where the nature of the design would permit, concrete was placed continuously from the foundation bed to the finished top, to prevent a horizontal plane of weakness, otherwise, horizontal keys were placed about 2 to 2½ ft. wide and about 1½ ft. deep. In the wicket pass and weir, care was taken not to permit stoppage closer than 8 ft. from the sill level, thereby insuring a monolith with sufficient weight to hold the wickets. The concrete sections of the bear-traps were placed continuously from bottom to top, except the small parts immediately about the hinges.

After Lock and Dam No. 18 were completed, tests for seepage and hydrostatic head were made by drilling several holes through the lock river wall near the middle of the section and observing the rate of filling and height of rise. In most cases, so little seepage occurred that the upward pressure against the base of the wall was believed to be negligible. Only one hole filled rapidly, a full head from the upper pool being possible. Since the blue shale foundation under that wall is of the same nature and quality as the foundation of the adjacent part of the pass, these tests indicated the possibility of a head against the base of some part of the pass masonry; and the stability of the pass may be due to the anchor-bolts. Experience and observation confirm the writer's belief in the importance and advisability of the use of anchor-bolts.

In August, 1912, after the dam had been in operation for two years, the bed-rock at the toe of the down-stream face of the pass foundation was examined, and no cutting or wear could be detected. Fig. 8 is a view of the completed Lock and Dam No. 18.

Cost of Masonry and Excavation, Lock No. 18.—A tabulation of estimated quantities, contract prices, and amounts, together with the actual cost of the completed work for lock and guide-wall masonry, is given in Table 5. The cost figures were furnished by C. H. Wright, Local Manager for the Contracting Company.

TABLE 5.

Item.	Quantity.	Contract.		Cost to Contractor.	
		Unit price.	Amount.	Unit§ price.	Amount.
Grubbing and clearing, in acres	5.5	$ 25.00	$ 137.50	$ 25.00	$ 137.50

* Rock excavation less in section than 4 sq. ft. and 10 ft. below low water.

† This was the principal work done in 1905; the cost includes a large amount for superintendence and management.

‡ The cost here given is for labor of laying only; the cost of the pipe delivered on the work was not obtainable.

§ The unit cost to the contractor does not include shipment of plant to work, interest on investment, insurance, cost of bonds, deterioration in plant, or general office expense. In this cost was included all labor, superintendence, and clerical accounts at the work, materials and everything of expense, except cost of machinery moved to this work from other jobs of the contracting company. Most of the machinery was provided in this manner. The cost of improvements to machinery, repairs, and maintenance and some new pieces of machinery were included.

Operation of Dam No. 18.

Land for Lock and Abutment.—When the location of Dam No. 18 had been definitely decided on, 5.5 acres of land were purchased at a fair farm valuation, above the top of the bank on the lock shore, including the banks up and down stream to the ends of the guide-walls, together with 3.1 acres on the abutment shore, for use of construction. Long delay in making purchases after locating

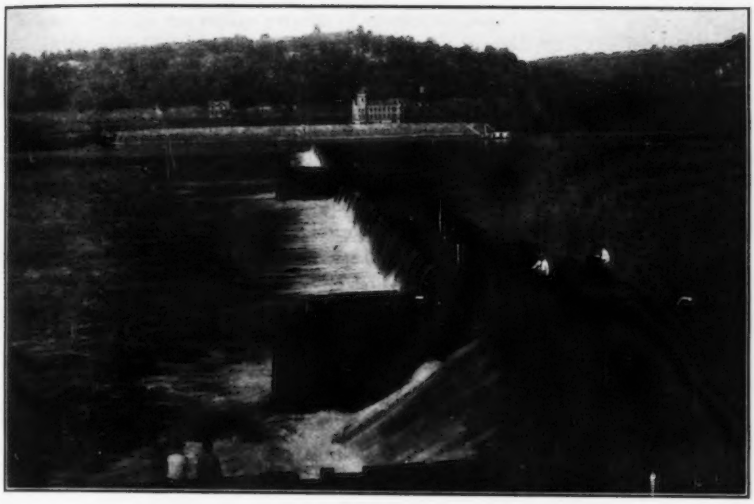

FIG. 8.—VIEW OF COMPLETED LOCK AND DAM NO. 18, OHIO RIVER.

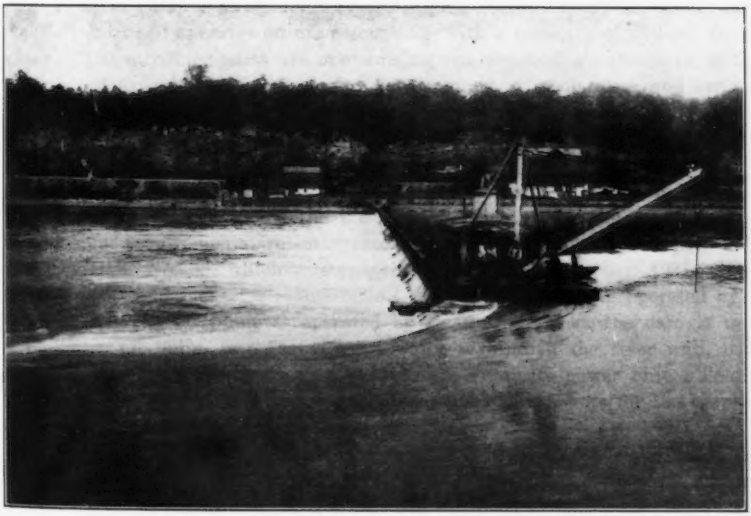

FIG. 9.—VIEW OF MANEUVER BOAT.

the lock sometimes results in paying two or three times the farm value, or resorting to the expensive process of condemnation.

Although the purchase was quite large, compared with the lands acquired for the up-river dams, it was found that more land was needed. In 1910, the District Officer, Maj.* F. W. Altstaetter, Corps of Engineers, U. S. A., M. Am. Soc. C. E., authorized the parking of all the land between the slope of the lock esplanade and well back of the rear line of the lockmen's dwellings, and further authorized the purchase of several additional acres of pasturage.

The writer believes it is wise and to the interest of the Government to arrange such facilities for employees, in order to supply commodities and give remunerative exercise within easy call of duty. These accommodations interfere in no way with their duties, because during many hours they have nothing else to do except wait for boats.

Lock Houses.—Two residences were built having basements of concrete, first story of brick, second story of terra cotta, tile roof with attic finished for storage, furnace in cellars and equipped for hot air, natural gas for light and heat, hot and cold water, with three rooms on each floor, bath on second floor, and laundry in basement. The buildings complete cost about $7 000 each. They are used by the lock-master and chief engineman with their families. All the other employees live in their own homes and come daily to work. Men who do not live within calling distance of a mile are required to have telephone connection with the lock-master's office.

Power Plant.—The operating power plant for the lock and dam consists of two 80-h.p. gas engines, each being sufficient for operation, thus eliminating as nearly as possible any possibility of stopping traffic through the lock. Each is belted to and operates an air compressor with a capacity of 300 cu. ft. per min. The auxiliary parts are one starting engine, four air receivers, with a combined capacity of 1 500 cu. ft., an air pump, a steel tower and tank on the hillside for water supply to the power house, lock, and dwellings.

The lock-gates are operated from a wire line winch with an air-operating engine having a pull capacity of 50 000 lb. in either direction. Each engine is provided with an auxiliary receiver. Where a reliable fuel supply can be obtained, the gas engine is the ideal power machine for the operation of a lock, since requirements are intermittent and, usually, of short duration.

At Dam No. 33, which was opened for service in October, 1921, all the valve jacks and jacks for maneuvering the mitered gates are operated by oil pressure. The oil pump is operated by steam, and when the dam is up, a duplicate oil pump is operated by a water turbine in the river wall, using water from the upper pool, thus providing a duplicate power unit. The use of compressed air is thus reduced to occasional requirements for the bear-trap operation and for signals on the lock walls.

Maneuver Boat.—The maneuver boat is a very substantially built deck barge, 60 by 22 ft., with a cabin 14 ft. wide by 24 ft. long, covering the principal pieces of machinery. The deck when equipped ready for operation stands about 14 in. above the surface of the water and the timber fenders, 6 by 15 in. The principal equipment for the boat consists of one triple-drum reversible

* Now Col., U. S. A. (*Retired*).

hoist engine with three winches, double 9 by 12-in. cylinders and pony drum for slewing the derrick, rigged with ½-in. wire line; one vertical 40-h. p. boiler; one stiff-leg derrick with boom located mid-deck near the bow; one outrigger sheave projecting from the bow for carrying the ½-in. line used in raising and lowering wickets; one steam capstan near the stern with an engine for operating, which carries the line for maneuvering the boat; a boiler-feed pump, a bilge pump, a steam siphon, and a hand pump. The smaller equipment is a wicket raising pole, an extra heavy raising pole, a wicket tripping pole, pike poles, skiffs and oars, 2-in. manila stern line, 750 ft. long, two 1½-in. manila side lines, 100 ft. long, several hand lines ¾ in., 1 in., and 1¼ in., one anchor, and one tarpaulin.

The cost of the boat and the principal equipment in 1909 was, as follows:

Deck barge, ready for equipment	$3 800.00
Engine and boiler complete	1 525.00
Wire lines for derrick	108.14
Wire rope sheaves, etc.	53.10
Spuds, six	170.00
Duplex piston pump, 9 by 5¼ in.	50.00
Orange peel bucket, 15 cu. ft.	499.00
Total	$6 205.74

An electric generator with incandescent and arc lights, with the necessary auxiliary parts, has since been added.

Maneuvers.—The three principal maneuvers of the lock and dam consist of: (1) operation of the lock when the dam is up for the passage of boats; (2) raising of the dam; and (3) lowering of the dam.

The annual force maintained is ten men, which force is supplemented by several additional laborers when the dam is up during the summer and fall. The annual force consists of one lock-master, three enginemen, one dam-tender and five lock-men. Each is an expert at one of the mechanical trades or other useful work, aside from the duties indicated by his position. With spare parts and materials for the machines and structures, this force maintains the lock and dam and appurtenances without additional help, except extra labor engaged locally.

The ordinary maneuvers of the lock for the passage of boats are the same as those required of locks with fixed dams. The usual time for the passage of a boat through the lock is from 7 to 12 min. The time required for the different operations is about, as follows:

Closing gate	1 min. to 1½ min.
Filling or emptying lock chamber	1 " " 4 "
Opening gate	1 " " 1½ "
Departure of boat	4 " " 5 "
Total	7 min. to 12 min.

After the winter floods, or after a summer flood of unusual duration, it requires from 1 to 2 days' time of the entire lock force with a maneuver boat

to remove the deposit from each of the lock-gate recesses, and to clean the gates, engine, and engine pit, and place them in a serviceable condition. It requires a day or more to raise the weir and put the maneuver boat in position to raise the pass. The raising of the pass usually requires from 6 hours to 1 day. Fig. 9 is a view of the maneuver boat raising the pass of Dam No. 1. A wicket prop is being raised with pike pole on butt ready to right the wicket the instant the prop drops over the hurter-step. Since it is desirable both for workmen and navigators of boats to have this maneuver made by daylight, the weir is put in readiness, and the raising of the pass wickets for final closure is usually started in the early forenoon. Raising the bear-traps usually requires only a few minutes by the head of water in the upper pool. The weir wickets are easily "righted up" from the "swing" or raised and put up as desired, if done before there is more than 4 or 5 ft. of head. With from 5 to 10 ft. of head, the work becomes much more difficult.

It is possible to lower the pass in from 2 to 3 hours, but it usually requires from 4 to 8 hours. On very rapid rises, the weir is sometimes lowered at the same time as the pass; but the lowering of the last weir wickets is usually left until the pass is down. The lowering of Dam No. 18 pass usually proceeds from the lock wall to the weir and the raising in the reverse direction. Some dams on the river make these maneuvers in the reverse order.

Maneuvering the Weir.—In 1912, Lockmaster Rowe reported on the maneuver of the dam, as follows:

"Ordinarily, we raise the service bridge with the maneuver boat as the river falls and the time approaches for raising the pass.

"When the maneuver boat is in position at the abutment end of the weir, the boom of the derrick is lowered until the main fall is directly over the chain connected with the section of bridge to be raised. A hook constructed so that it will engage with the bridge chain at any point is used on the main fall. One man is stationed in a yawl, whose duty it is to connect this hook with the bridge chain as low down in the water as convenient. This section of the bridge is then raised with the main fall of the derrick, until the end of the apron is on a level with the top of bridge on pier. A 1½-in. manila rope, with an iron hook on the end, is then hooked into the ring on the end of the apron. This rope passes through a snatch-block on the pier back of the starting point, or on preceding section of bridge, then back through fixed sheave on forward end of boat and is pulled with steam capstan. The rope swings the section of bridge back until the bent is perpendicular. The apron is held up at the proper height with the derrick until in position for dropping down over pins in pier or in preceding section. About four sections can be raised with boat in the same position. The boat lies below the bridge with bow up stream. This maneuver requires seven men: One for operating engine, one for operating capstan, one in yawl for engaging hook, two on bridge for connecting up sections, moving snatch-block, etc., and two on deck of boat for handling lines, moving boat, etc. The bridge can be raised in this manner in one-half the time required for raising it with the winch.

"When the bridge is up, the maneuver boat is then moved over to the pass and two crews are organized so that the weir wickets and pass wickets can be raised at the same time. [Fig. 10 shows a wicket-sinking arrangement for weir service bridge for Dam No. 18].

"In raising the weir wickets with the winch, the duties of the men are about as follows: One man for operating the gasoline engine, clutch-coupling

and foot-brake; one for placing chain on wheel and keeping it from getting fouled in the gear; two for moving and clamping car on track, handling chains, etc. The weir wickets are left on swing until they are all up in that position, and then the same crew rights them up with pike poles after the navigation pass is closed.

"By leaving the weir on swing and both bear-traps down, we rarely have more than 2 ft. of head when closing the pass.

"There is other work to be done aside from that mentioned in raising and lowering the dam, sunken logs, boulders, etc., are encountered, props are found to be out of hurters, hurters have to be cleaned out, etc. When these things are encountered, all the members of the crew work to adjust them. One man who handles the catching hook will sometimes dive down and lift a prop over into a hurter by hand, rather than make the maneuver again."

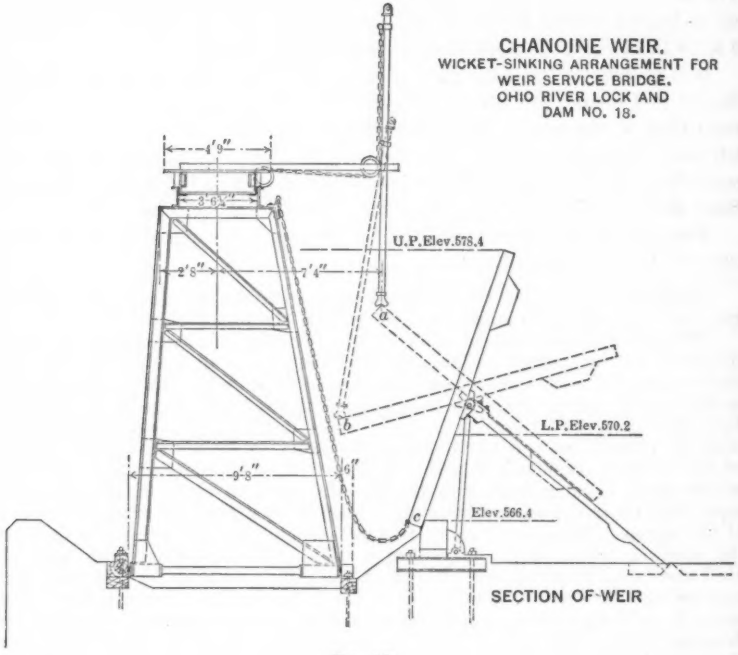

FIG. 10.

Due to the ease of operating the traps and the difficulty of moving the maneuver boat around the traps and their piers, in a dam without a bridge and which has the traps near mid-stream, between the wicket navigation pass and wicket weir, when the dam is up or after raising is started, the lockmen at some of the dams, depend almost entirely on the traps for regulating the pool and neglect to use the weir for that purpose, the function for which it was built.

This difficulty makes it now appear that on those dams having abutment shores of ledge rock, or ledge within 10 or 15 ft. of the sill level, a desirable

location for the traps would have been next to the abutment, thereby placing the weir wickets next to the pass wickets.

Except for the excessive cost of the traps, an ideal arrangement would be to abandon the wicket weir and substitute bear-traps having sufficient waterway to regulate the pools for a natural 10 or 11-ft. stage discharge.

In 1914, the writer had the 15-ft. trap in Dam No. 18 cleaned and repainted. His report of this work is as follows:

When unwatering was completed, a deposit estimated to be about 65 cu. yd. was found in the recess under the two leaves. The deposit on the upper side of the area was largely of silt, but on the lower side near the lower hinge, it was principally gravel ranging from the size of a pea to that of an acorn. Much of the gravel was clean washed and lay 2 ft. or more in depth on the recess floor. In all the pockets of the lower leaf, the deposit was from 14 to 18 in. deep, composed of silt, containing little or no gravel.

On the top skin of the lower leaf, from 60 to 70% of the metal was bare of paint, the remainder being fairly well covered with the shop coat. The under side of the lower skin and the exposed metal on the under side of both leaves were practically bare of paint. On the inside of the pockets of the lower leaf, from 80 to 90% of the metal was covered with paint. After being cleaned, there was slight indication of the metal being pitted by rust.

The two wooden seals were almost destroyed. The lower flange of the lower end of the easterly girder in the lower leaf was bent from 4 to 10 ft. in front of the hinge; the lower flange of one of the other girders was slightly bent; thirteen girder web-plates were bent, and the two lower ones in the easterly girder over the bent flange, were badly buckled; eleven of the cross web-plates were slightly bent; eighteen plates of the lower skin were bent; two bolts near one of the hinges were out, but no sheared rivets or loose rivet-heads were found.

Since the trap had been operated successfully for some time without the water seals, they were not replaced. The damage to the metal work was not considered sufficient to affect seriously its strength, therefore, no attempt was made to repair it.

The approximate cost for all this work was about, as follows:

Labor	$1 158.43
Painting materials	173.01
Lumber	118.48
Supplies, caulking material, etc.	35.00
Miscellaneous	78.57
Gas	85.00
Coal	100.63
Total	$1 649.12

In order to ameliorate the adverse conditions described, the following changes for future plans were suggested:

"(*a*) In each of the piers there should be a pump-well, at least 4 by 6 ft., to admit of using a larger pulsometer. Directly under each of the manholes in the lower leaf, next to the piers, there should be a similar sump.

"(*b*) The piers should be long enough at the lower end to give a plain surface bearing for the end coffer-dam needles. About the perimeter of the lower culvert portals there should be a recess with a plain surface at least 6 in. in width, in order to make the bulkhead more easily fitted and more easily caulked.

"(*c*) The greatest danger from the deposit underneath the leaves is believed to be in lifting or holding the lower leaf above its natural position on the floor, thereby throwing undue strains on some of the girders or creating a short lever arm and bringing excessive pull on some of the hinges. This is especially dangerous where the support under the girders is near the lower end hinges. This may be prevented by placing the upper and lower water passages between the bear-trap recess and the culverts close to the hinges. It is also advisable to make those openings from 3 to 5 ft. high instead of 2½ ft. Should this method not entirely relieve the trouble, in new construction a pipe or culvert laid just below the line of the hinges with an opening alongside each hinge leading from the bear-trap recess to the culvert no doubt could be made effective in washing out any deposit which might occur.

"(*d*) In order to clean the pockets of the lower leaf more easily it is desirable to substitute channels and angles for some of the web-plates. The elimination of this method of bracing and the elimination of half the plates would make the cleaning very much easier."

As the writer was not able to find any record of a trap having been unwatered, cleaned, and painted elsewhere, somewhat better progress could be made on another similar job with this experience.

Maneuvering Pass.—The first sixteen wickets of the pass are raised with the maneuver boat lashed to the pier. After they are up, the maneuver boat is laid alongside them, and the raising proceeds as described by the writer, in his report of May, 1912, as follows:

"The head of the boat is brought up so that the front edge of the bow is within a few inches of being flush with the last wicket raised, the boat being held in place by a stern line to the pier, and two side lines made fast to convenient wickets—one near the bow and one near the stern. With the boat thus prepared and held in position, the lockman casts the raising hook to land on the upper face of the wicket to be raised. After striking the wicket it is drawn along it by a ½-in. wire line wound on one of the drums of the hoisting engine, until the hook engages in the handhold at the butt of the wicket. The wicket is then drawn up until the prop is heard to fall into the step of the hurter. At that instant the lockman disengages the raising hook, and another man with a pike pole forces the butt of the wicket down against the pass sill. At the instant the wicket strikes the sill, a third lockman, tending the stern line, releases 4 ft. of slack, and the current carries the boat forward the width of a wicket. At the same time the engine-man takes up 4 ft. of the head side line while the lockman on the head of the boat maneuvers the side line on the winches of the engine. This movement usually requires from 10 to 15 sec. from the time the butt of the wicket strikes the sill. In general, it is not necessary to operate the spuds in either raising or lowering the wickets During this maneuver the stern spud and upper side spud are raised and hooked up. The lower side spud is left down just far enough to engage the wicket. By so doing, it serves two purposes: The boat is made steady, and as it engages the wicket below the axis, it prevents it going on swing."

In lowering the pass wickets the movements of the boat are a reverse of those described previously. The lockman engages the lowering hook in the upper hand hold of the wicket, and signals to the engine-man to pull on the

line attached to the hook. The instant the lockman hears the prop drop out of the step of the hurter, he disengages the hook, and the wicket, if not obstructed, is carried gently down by the current into position below the sill. At the instant he disengages the hook, the boat is brought in position for lowering another wicket.

The maneuvers of the wickets are often interfered with by obstructions of gravel, boulders, and driftwood. The methods of overcoming these difficulties are only learned by experience.

Water Supply.—The water supply was taken by an air-lift pump from the rear end of the upper gate recess and by sedimentation gave a potable water. At sites where a natural supply is not found, the filter should be constructed at a convenient place in the lock coffer-dam. For Locks Nos. 20 and 33, and for some of the others, filters are constructed in the angle between the upper face of the navigable pass and the river wall.

Signal Lights.—Signal lights are maintained for indicating whether the dam is up or down, and the position of the ends of the river wall and bear-trap piers. The number of lights, their positions, and colors are prescribed by the Engineer of the Light House Department. The lights are carried on standards. Supports of concrete and steel have been tried, but have not yet proven entirely satisfactory. The supports after being submerged and the lights extinguished are a menace to navigation as long as the depth of water is too shallow to prevent boats passing safely over them. During periods of swift current, drift, and ice, it has not been easy to maintain floating supports for carrying the lights. In April, 1915, a passenger steamer hit one of the lower towers on Lock No. 19, sank within a few minutes, and about 17 people were drowned.

Snubbing Posts.—The next greatest menace to navigation are the snubbing posts on lock walls and piers. In March, 1907, a steamer hit the second snubbing post (from head) on the river wall of Lock No. 18 in clear weather, when there was about a foot of water over it, and sank within 15 min. on the head of Neals Island, with several people narrowly escaping drowning. At the time, the water breaking on the nose of the wall clearly marked its position. The light towers and snubbing posts continue to be the greatest source of danger to the navigation of the locks and dams.

Disposition of Drift.—It has been the custom to dispose of the drift by hand or derrick or by letting down one or more wickets or a bear-trap. The writer believes that all big logs and trees should be landed on shore, cut up, and burned, thereby preventing injury to passing boats, or further attention at the next dam below.

The writer wishes to make acknowledgment of courtesies extended by Col. Earl I. Brown, Corps of Engineers, U. S. A., M. Am. Soc. C. E., for access to the records of the first Cincinnati District, as supplemental assistance in the preparation of this paper.

DISCUSSION

THOMAS P. ROBERTS,* ESQ. (by letter).—Referring to the late W. Milnor Roberts, Past-President, Am. Soc. C. E., the author states that Mr. Roberts recommended locks with movable tops on Ohio River dams. The fact is, he never recommended "movable tops" on dams, as such term is understood by river engineers. In 1839, in a report to the Monongahela Navigation Company, he advocated the extension of locks with fixed dams for the Ohio River, such as he was constructing on the Monongahela. Later, in 1857, in a paper published by the Franklin Institute, Mr. Roberts repeated more fully the same recommendation. In 1866, he was made one of the two U. S. Civil Engineers, authorized by Act of Congress, and assigned to the Ohio River to complete the survey of that stream from Pittsburgh, Pa., to Cairo, Ill., and to undertake minor improvements for the immediate betterment of navigation. The chief object of his employment by the Government was to obtain his views on the various schemes, or projects, which had been referred to the Chief of Engineers for the radical improvement of the Ohio.

In his final report, dated April 21, 1870, referring to the dams he was recommending, Mr. Roberts sanctioned the idea of placing in them "chutes" 300 ft. wide, for the benefit of descending coal fleets, thus making navigation practicable for them, even during moderate rises of the river. The chutes were not described in detail in his report, but, to the writer, he stated that chute shutters might be made, say, 3 ft. deep in dams of 6-ft. lift, such as were contemplated by him. The shutters were to be raised by a shaft operated from the lock wall, the shaft turning geared wheels at proper intervals beneath the shutters. The time required to raise them against the water pressure was a matter of indifference, the longer the time, the less the power required. He clung to this idea even after meeting the late Col. William E. Merrill, Corps of Engineers, U. S. A., M. Am. Soc. C. E., his successor in charge of the Ohio River, who had but recently returned from France, where he had seen and was greatly pleased with the Chanoine wickets on the Marne and Upper Seine Rivers. Concerning the project of Mr. Alonzo Livermore who had constructed the locks and dams on the Green River, in Kentucky, Mr. Roberts made no objection to placing a contrivance in the form of a down-river extension of chutes in dams, arranged so that current velocities could be reduced sufficiently to enable ascending steamers to pass through the chutes. Mr. Livermore was to demonstrate the feasibility of his project, which, although theoretically practicable for clear water, might not have been advisable for rivers in which snags and drift complicated the problem during floods.

In an historical review of other projects for river improvement, submitted to Mr. Roberts for his opinion, it may be permissible to refer briefly to some of them. The most important of these projects was suggested, years prior to the Civil War, by Col. Charles Ellet, a distinguished writer on river hydraulics, as well as on railroads and bridges.

Based on ten years' records of rainfall and river discharge at Wheeling, W. Va., made under his personal supervision, Col. Ellet demonstrated that

* U. S. Engr. Office, Pittsburgh, Pa.

a 6-ft. minimum to 9-ft. maximum stage could be permanently maintained on the Upper Ohio, provided the excess of flood water on tributaries could be stored in reservoirs. This project was so ably set forth by Col. Ellet and Mr. Elwood Morris, as to attract much public attention and was even favorably considered by Congress which was about to appropriate a large sum for starting surveys for reservoirs, when Mr. Roberts, almost alone in his opposition, interposed with his pamphlet entitled, "Practical Views on Ohio River Improvement". He showed that, in 1847, to have had full control of storm waters, the reservoirs above Wheeling should have had a capacity of more than one trillion cubic feet. His strongest point was that the records indicated the probability that some of the more important reservoirs would have been full when certain floods occurred. Other river engineers, including Col. C. McD. Townsend, U. S. A. (*Retired*), M. Am. Soc. C. E., formerly President of the Mississippi River Commission, have since demonstrated that, as great river floods frequently originate from comparatively limited areas, for instance, such as have created very high floods at Cairo, such floods might be aggravated by waste waters from reservoirs at the head of the Ohio, etc. It has been proved that to reduce materially the height of great floods at Pittsburgh, restraining reservoirs should be as near as possible to the city, for the flood-producing storms reaching Western Pennsylvania are only rarely more than 90 miles in width of excessive precipitation. However, on rare occasions, Nature doubles, or even trebles, what is termed her excessive precipitation, as appeared in 1913 over Northern Indiana and Ohio, just covering about one-eighth of the Allegheny River water-shed. That one-eighth, however, with a precipitation of from 7 to 9 in., produced a flood which at Pittsburgh, 100 miles below, was greater in discharge than any preceding flood developed from more than triple the same storm area. Had the 1913 storm moved eastward only 80 miles farther, careful study indicates that, at Pittsburgh, the flood would have been at least 15 ft. higher than the record flood of 1907. It is useless to attempt to estimate the damages which would have resulted from such a flood to the towns, bridges, etc., above Pittsburgh. The 200 acres of low land embraced in the business section of that city, with currents of from 8 to 10 miles per hour, of from 12 to 14 ft. in depth, through its streets, can be imagined if not described. What would have been left for salvage of the city would have been chiefly steel beams, protruding from a great area of gravel, building materials, etc. To talk of restraining reservoirs for such floods, at least for the area above Pittsburgh, is waste of time. From the evidence of the topography of the Allegheny Valley, glacial drift remains, etc., no such flood has occurred at Pittsburgh since the last flood waves of the glacial epoch passed along the Upper Ohio Valley not less than 10 000 years ago.

Wrong impressions of the transportation capacity of the Ohio River, when finally improved, should not be perpetuated in the publications of the Society. It is of the first importance that Congress should not vote away public funds on projects that will not adequately benefit the public interests. More and more it is being demonstrated that without the utilization of the inland waterways to cheapen transportation to the seaboard, all hope of a

world-wide extension of commerce must be abandoned. The railways now staggering under the loads imposed on them, would be greatly relieved if some, such as coal, and other items of low intrinsic value, could be taken from them.

It is unfortunate that the river engineers of the United States competent to portray the advantages of waterways are, in a way, debarred from promulgating their views, but must usually confine themselves to the engineering duties assigned them. On the subject of the real potential capacity of the Ohio when improved throughout its entire length, Mr. Hall writes as follows:

"The capacity of the river for package and barge freight, when the improvement is completed, would easily be 25 000 000 tons annually and possibly double or treble that quantity. However, during the months the dams are up, the lockage capacity would be much below that rate."

From such a statement the inference is that locks 600 ft. long by 110 ft. wide (the same width as provided for the Panama Canal), and 9 ft. deep on gate-sills, would be "much below" a capacity of 25 000 000 tons annually.

In the Pittsburgh Engineer District there are included ten locks 600 ft. by 110 ft. on the Ohio, three locks and dams on the Allegheny River, and fifteen locks and dams on the Monongahela River. Six of the dams on the Monongahela, next in order above Pittsburgh, are provided with twin parallel locks averaging a lift of about 9 ft., with available chamber dimensions of 360 ft. by 56 ft., with limiting depth, at one lock, of 9.2 ft. on gate-sills, up to, and including locks, at Dam No. 6. Yet, during 1920, with practically all the traffic being compelled to pass through the locks, there was accommodated 24 000 000 tons. The lock most used was at Dam No. 3, where for three months during 1920, the traffic was confined to one lock chamber. During this period of three months, there were passed through the single lock in one day 93 000 tons, with not quite all the time available for locking utilized. The tonnage was nearly all down stream, while empty fleets (which might as well have been loaded) passed upward. Upward bound fleets meeting descending fleets have both been passed through Lock No. 3 in 35 min., although 40 min. are usually allowed (single steamers, of course, in both directions in considerable less time). Had this traffic through a single lock at Dam No. 3 been maintained for a year of 280 days, it would have amounted to nearly 26 000 000 tons.

Only stern-wheel boats equipped with balanced rudders are used on the Monongahela. When backing their wheels, these boats develop an enormous steering power, and are capable of doing such a business safely in the narrow confines of lock approaches. Collisions of vessels or serious damages to lock-gates are rare occurrences on the Monongahela. "Tunnel boats", or independent double-screw boats, will probably never be built for the rivers about Pittsburgh, as they are all deficient in steering power. Pittsburgh is the seat of inland waterway transportation, more than equalling the present tonnage of the entire Mississippi and its tributaries below the city. Here, also, were made, at much cost, experiments with bear-traps, Chanoine wickets, roller lock-gates, etc., leading up to further improvements elsewhere on the river. There is no better school than "the school of experience".

The Monongahela locks will now be compared with those built, or in process of construction, on the Ohio. Fleets of 9 000 tons have been frequently passed down the Ohio through Locks Nos. 1, 2, and 3, which locks have the same dimensions as all locks on the river below to Louisville, Ky., 600 miles below Pittsburgh. These fleets were passed through these locks, usually in 20 min., and ascending fleets meeting descending fleets, including the time required in filling the lock chambers, were passed in 45 min. Considering adverse winds, and contingencies of freshet currents approaching locks, it is considered safe to say that fully 10 000 tons per 50 min. could be passed down the river, and a theoretical tonnage of nearly equal amount might be passed up. Therefore, 50 min. would permit of twenty-eight down, and twenty-eight up, lockages per diem. Ignoring up-stream tonnage and restricting down lockages to 8 000 tons would make a possible down tonnage of 224 000 tons daily, as compared with the 93 000 tons daily for a single lock on the Monongahela, previously referred to.

The writer has been in charge for more than 20 years of Monongahela locks and dams and is fully aware of the likelihood of locks being closed for repairs, necessity for which at times may put a lock out of commission for extended periods. The Ohio locks, however, have an important advantage over those on the Monongahela, where there is no open-river navigation, in the fact that, on the Ohio, repair work is often practicable during the periods of open-river navigation, or when the locks would not be used by passing vessels. Doubtless, however, Ohio River dams, in due time, as necessity arises, will be provided with second locks, such as are already constructed at the Emsworth Dam on the Ohio, 9 miles below Pittsburgh.

As open-river conditions will be maintained longer on the Ohio River below Wheeling, 90 miles below Pittsburgh, than above that point, there will be a greatly lessened dependence on locks below in the river to Cairo. With open-river conditions, the capacity of the Ohio for traffic, of course, would be exceedingly great, but one must not be unmindful of the fact that, for a regular annual traffic on the Ohio, the worst low-water conditions should be assumed, for the traffic is not dependent on weather conditions, but comes from human needs—"the law of supply and demand." It can be depended on that the capacity of the river when the growth of traffic demands it, can be made considerably more than 100 000 000 tons per annum passing any given point, or more than four times the present annual traffic of the Monongahela River with its small locks and no open-river navigation.

At the risk of unduly prolonging this discussion, the writer urges attention to an important topic raised by Mr. Hall in the last paragraph of page 97. It concerns, as he says, the "fallacy of free rivers" improved and maintained by the Government and left for "Tom, Dick, and Harry" to rival each other in picking up package freight and cutting each other's throats with lower and lower rates, until finally no profit is possible. At present, the Ohio is, to a considerable extent, only a playground for the owners of small locally owned boats engaged in short-distance transportation. Under such circumstances, no responsible companies will undertake to construct on a large scale, first-class

terminals and operate steamer and barge lines on schedule time, and never will, until something is done under the auspices of the Government. The writer in saying this does not wish to discredit several small companies recently organized to place steamers on the river above Cincinnati to Pittsburgh. They are doing well and their business is increasing.

In time, there must come on the Ohio, steel barge lines towed in fleets for long-distance transportation, that is, freight towed in fleets separate from the miscellaneous light traffic possible for fast passenger boats, before traffic worthy of attention will be developed. The barges will have to be loaded at the mills and mines in 500 to 1 000-ton lots, otherwise, the old low ton-mile rate will never be revived. Rivers in this respect are in no way different from railways. However, with rivers, no maintenance of "roadbed" is necessary.

The writer, several years ago, stated in a published article that the freedom of navigation on the Western rivers had led to almost the entire extinction of traffic on them. Nevertheless, it is best that the rivers be left free, if for no other than physiological reasons. To charter companies, would lead to the development of animosities fraught with mischief.

To revive interest in the rivers, the writer proposed a plan somewhat as follows: First, the appointment of a commission by the Government directed to visit every important commercial or manufacturing community along the rivers (say, for a trial section, the Ohio between Pittsburgh and Louisville, 600 miles), the navigable tributary streams to be included, to obtain information as to their commercial or manufacturing resources, tonnage traffic, etc. Second, that the commission be authorized to meet boards of trade or prominent business men and inform them that for the cost of modern terminals and railway connections the Government would subscribe 51%, provided the citizens of the locality subscribe 49% of said cost, the Government guaranteeing 3½% on all private investments (approved by the commission, and, later, of course, indorsed by the National authorities). Third, that boat lines, steamers, barges, repair yards, etc., be organized in the large cities on the same basis, no profit in the operation of boat lines or terminals to be in excess of 3½% on the total investment of capital including maintenance, renewal of plants, etc.; any further profit desired by private subscribers to be found only in the extension of their business by trading with distant markets secured to them by the boat lines.

The writer's conviction was, and is, that this is the best and surest method of interesting vast numbers of people in the benefits of inland navigation. Any small companies desiring to compete with the semi-national boat lines should be allowed to do so, except that they should pay proper charges, where they utilize the National terminals. All the Government desires is to develop the usefulness of the rivers. If private boat companies can be organized to do business, on a reasonably large scale along the rivers, at rates lower than the official rates, then the "official" boats can be withdrawn from the trade and utilized elsewhere. Private subscribers to terminal landings, where such would be abandoned for lack of income, should be refunded.

With this proposition nothing would be done by the Government unless it was amply assured by the data secured by the investigating commission.

EARL I. BROWN,* M. AM. SOC. C. E. (by letter).—The improvement of the Ohio River for navigation purposes, under the present project, is a problem of intense interest to all engineers who have been connected therewith. Literature on the subject describing the locks and dams and the methods of construction used to meet the special problems that arise in connection therewith, is scarce, and Mr. Hall's paper is a valuable contribution to it.

As explained by the author, the project for improvement has been carried forward progressively from Pittsburgh, Pa., toward the lower end of the river, to such an extent that practically all the locks and dams between Pittsburgh and Louisville, Ky., either have been completed or placed under construction, as well as several between Louisville and Henderson, Ky. The experience gained in the construction of these locks and dams has been such as more or less to crystallize and systematize the methods of construction for these structures. The methods described by the author for Dam No. 18 may be taken as representative of the later practice in the construction of locks and dams on the upper part of the Ohio River as far down as Dam No. 31, at Portsmouth, Ohio.

Practically all the dams from Pittsburgh to, and including, Dam No. 31, are founded on rock. This fact simplifies the construction on account of the inability of the current to erode the bottom of the river when the bed is contracted by the coffer-dams utilized for construction purposes. In several instances, on dams below Dam No. 31, constructed on sand and gravel foundations, extensive erosion of the banks and bed of the stream has occurred during freshets, due to the presence of the coffer-dams. This has resulted in difficult and expensive work in filling the eroded area and in replacing damaged parts of the coffer-dam and other structures.

The quantity of sediment carried by the river in times of flood also varies greatly in different parts of the river, increasing from the head-waters downward. In the upper half of the river, construction work was not greatly hindered by deposits in the working area within the coffer-dams during floods, but, in the middle and lower sections, these deposits become very great and cause considerable loss of time and great expense for their removal after the freshets subside and before construction operations may be resumed. Dam No. 48, near Henderson, Ky., is the lowest one of the series on which any work has yet been attempted, and its history has been one of great difficulties encountered and unexpected cost from shifting sand and damage by flood and deposits.

These conditions have led to a reconsideration of the project, with a view of meeting these increasing difficulties by some modification of the plan. Studies have been made with reference to the possible elimination of all locks and dams below Dam No. 49 and a substitution therefor of a system of improvement by regulation. It has been pretty well established that a system of regulation by open channel work below Dam No. 49 is feasible, but that the expense of such a system of regulation would exceed the cost of locks and dams above the mouth of the Tennessee River at Paducah, Ky. Below

* Col., Corps of Engrs., U. S. A., Wilmington, Del.

Paducah, it is probable that improvement by regulation would not be more than 50% of the cost of improvement by locks and dams. This is due to the fact that this part of the river, about 47 miles in length, is affected by back-water from the Mississippi River at Cairo, and the low-water discharge is practically doubled since the Ohio receives the discharge from the Tennessee River, the low-water discharge of which is practically equal to that of the Ohio. It may be stated, therefore, that these studies indicate that the project might be modified further to advantage, by the elimination of Dams Nos. 53 and 54 in that section of the river between Paducah and Cairo.

By reason of shifting sand bottom, broad channel of the river, lack of rock foundation within reasonable reach of the surface, and small low-water discharge, the construction of dams from No. 48 downward will be difficult. Moreover, back-water from the Mississippi River extends its influence up the Ohio River at low water to great distances, practically to the location of Dam No. 49.

As the coffer-dams in which these structures are built cannot with safety be constructed to exclude freshets of more than 16 to 18 ft., the number of working days possible during the year depends on the number of days the river, at the site of the dam, is at and below these stages. In the upper part of the river, where construction has heretofore been carried on, the number of days the river is at and below these stages is relatively large, averaging well over 100 days per year. In contrast, an examination of the records of the stages of the river at Cairo, near the location of the proposed Dam No. 54, shows that the river is at and below an 18-ft. stage only about 60 days in the year, leaving only about 2 months available for active construction work. The present types of coffer-dam, therefore, would become increasingly inefficient as the work progresses down stream.

In those locks that are not founded on rock, certain modifications of features, previously considered to be standardized, have been found to be desirable. To prevent a leakage under these structures through the sand and gravel foundation, it has been found necessary to provide a cut-off wall of steel sheet-piling extending continuously across the river from the lock to the abutment and penetrating the bottom to a depth of from 30 to 40 ft. This cut-off wall is also carried entirely around the chamber of the lock so as to exclude leakage into the chamber. With this continuous cut-off wall, it has been found possible to omit the concrete floor of the lock, which has hitherto been provided, and to substitute therefor a layer of broken stone about 2½ ft. thick, at much less expense. Most of the locks heretofore constructed have been provided with a Poirée dam at each end, for the purpose of unwatering the lock when making repairs to the chamber and gates. It has been found feasible to omit this, utilizing instead a short section of ordinary box coffer, which can be placed in position in about the same time as the Poirée dam and which reduces the first cost of the lock by several thousand dollars.

Most of the locks heretofore constructed have been provided with rolling gates, which type was developed to suit local conditions on the Upper Ohio River. On the lower part of the river, many objections have developed to the

rolling gates, and it has now been definitely decided to construct no more dams with this type of gate, but to use instead the ordinary mitering gates. The principal objection to the rolling gate is the fact that it requires one or two weeks at the beginning of each season after the freshets subside to place the gates in commission, by reason of the difficulty experienced in removing deposits of mud and sand which accumulate in the gate recess. It has been found impracticable to seal these recesses sufficiently to exclude the deposits of fine mud and sand, which are carried by the winter floods and which increase greatly in quantity with distance down stream. This trouble does not occur with the mitering gates, and the expense of construction is not greatly different from that of the rolling gates.

In the operation of this system of locks and dams, much trouble has been experienced by reason of inability to raise the dams at stages higher than about 9 ft. This results in the impounding and holding back of the discharge of the river in the pools of those dams that are raised, with a consequent rapid falling off in the discharge of the river at points lower down. So great has this effect on the discharge of the river become, that at times much delay and obstruction to navigation has been experienced at and below Louisville, by reason of the manipulation of the dams at and above Cincinnati. As the number of dams in operation increase, the effect on the lower part of the river will become more and more marked, and, at times, may result in an almost complete absorption of the discharge of the river, if great care is not exercised in the raising of the upper dams.

To meet this difficulty, a comprehensive scheme of control of operating the dams will have to be devised, so that constant reports as to the stages of the river and variations of discharge may be received at a central point, at which will then be determined the proper time for the raising and lowering of all dams, thus regulating them so as to affect the discharge in the lower parts as little as possible. A telephone system is being provided, connecting all dams to a central point, which will probably be Cincinnati, and that will be the point from which this centralized control will be exercised. After some means can be devised whereby the dams can be raised at stages above 9 ft., much benefit will be gained, and it is understood that attempts are now being made to devise some method of raising the dams at higher stages.

On several of the locks and dams, experiments have been made in the use of steel sheet-piling for the construction of coffer-dams, with some degree of success in the matter of increasing the number of days on which construction operations can be begun. This experiment is being carried out most fully at Dam No. 34. It is hoped that additional information covering this mode of construction will soon be available.

William W. Harts,* M. Am. Soc. C. E. (by letter).—To those members of the Profession who are interested in the navigation of inland rivers, the author's painstaking and excellent paper should be welcome as a valuable addition to their information on this subject.

* Col., F. A., U. S. A., Coblenz, Germany.

Much has been written on the engineering projects undertaken on the Ohio River during the last fifty years, but it has been mainly since the adoption, in 1875, of the present method of slack-water by means of movable dams, that this river has acquired a great engineering interest. It may be stated positively that the present slack-water system of the Ohio River is unsurpassed anywhere in the world, for suitability to local conditions, practicability in operation, economy of cost and maintenance, and success in meeting physically the needs for which it was adopted.

For many years, much attention has been devoted to the details of this system, and examples of successful practice elsewhere in the world have been examined and studied and often combined with new inventions in a project for this stream, which now challenges the admiration of engineers generally for its excellence and success.

The east and west direction of the course of the Ohio, so fortunately parallel to the great east and west freight movement in the area south of the Great Lakes, together with the large deposits of coal along its head-waters, often on the very banks of its tributaries, gave an enormous importance to the navigation of this river in earlier years and stimulated the need of better channels and depths as the pressure for fuel increased in the West, and as the size and unwieldiness of coal fleets increased.

Already, some of the tributaries had been made the subject of engineering attention by the States through which they passed, and their steep slopes had been overcome during these earlier years by slack-water projects, using locks and fixed dams. Through these developments the coal on some of these tributaries could be brought out more easily during the year and held in pools ready to float down the Ohio in huge fleets on the spring floods, to supply the growing markets of the Lower Ohio and Mississippi Rivers.

This important traffic in coal, thus commenced, grew in later years to an enormous volume, reaching, in 1900, nearly 15 000 000 tons. It was only natural that it should have been the early aim of the Government engineers to use the well-known slack-water system, already applied to some of the tributaries, for application also to the Ohio River, but until the early objection to the fixed dams of the tributaries could be overcome nothing could be accomplished.

The Ohio is subject to extreme floods. Sometimes, as much as 70 ft. in range is recorded, and great injury and loss invariably result to the towns along the banks. Nothing could be allowed in the bed of this stream that would be likely to increase this range, and in the public mind fixed dams were objectionable for this reason. Large quantities of sand and mud are carried down at each freshet, which, it was feared by some, might fill the channels if fixed dams were used and thus ruin the existing navigable depths, and, furthermore, the pilots of the towboats which guided the great fleets of coal barges down the Ohio at high stages, would not consent to any obstruction that might make the management of these fleets more difficult at open-river stages. A movable dam of some type was believed to be necessary to meet these objections.

Accordingly, search was made everywhere for types, and the following were finally found to be the best suited to the condition, namely, wickets, such as the

Chanoine, needles, such as the Poirée, and bear-traps, an invention of the lumbermen who used this kind of dam to create an artificial wave to float out lumber rafts on the head-waters of streams of small flow. After trial on one of the tributaries, the needle type was abandoned for use on the Ohio, and bear-traps were adopted as a regular device for controlling levels.

The first dam was of the wicket type, of low lift, and was authorized by Congress in 1875 on the recommendation of the late Col. W. E. Merrill, Corps of Engineers, U. S. A., M. Am. Soc. C. E., who, with much justice, has been called the "Father of the Ohio River Navigation". Much study since the construction of the first dam has produced the present type of structure, and in 1910 the canalization of the entire river was authorized by Congress at a cost then estimated at $63 000 000. Before that time, the engineering features had been mainly standardized in practice, but new improvements were eagerly sought. The author's description of these standard designs, as applied to Lock and Dam No. 18, are clear and instructive. It is believed that a further discussion by him of his reference to the economics of the entire project as viewed under present conditions, would have been enlightening and profitable.

The enormous development of the steel industry in the Pittsburgh region and the corresponding increase in the demand for coal for smelting purposes have led to the more perfect control of the coal measures of the Western Pennsylvania regions by the steel companies, with a view to conserving the present stock. This has succeeded so well that a large volume of coal no longer seeks a market by the Ohio River; this export has been almost stopped, and coal is even imported to the Pittsburgh region from the West Virginia fields. Furthermore, the development of the Alabama coal mines and the discovery of oil in Oklahoma have reduced the fuel demands for Ohio River coal in the Lower Mississippi Valley. The low cost from the newer mines of Western Kentucky and Southern Illinois also reduces the demand for Pittsburgh coal. All these influences have had a marked effect on the commerce of the Ohio River of late years. In 1900, the commerce, principally coal, amounted to about 15 000 000 tons, whereas in 1920 it had fallen to about 5 000 000 tons. Thus, it appears that in about 20 years the commerce had dwindled to about one-third its former proportions, notwithstanding that, in the meantime, many troublesome shoals had been eliminated by the new locks and dams which were completed from time to time, thereby materially increasing facilities for navigation, as may be seen from the fact that thirty-three of the proposed fifty-four locks and dams had been completed by the latter date.

If the traffic diminishes, the overhead costs, being more nearly fixed, increase relatively, but are still a proper charge against the costs of water transportation. The main interest which the public, as a whole, has in works of this character, is in the saving that may be made over other kinds of transportation, in money or its equivalent. On no other basis can works of this class be justified economically. The overhead charges for interest on the first cost, depreciation, and other annual charges, together with the cost of maintenance of the channels by the public, is undeniably a part of this cost of transportation and must be added to the shipper's cost of water haulage to

ascertain whether the actual cost of transportation by water is less than by other means. A short computation should reveal the facts in this regard. If there is thus shown to be no saving or a loss in developing transportation by water rather than by other methods, all features considered, the enterprise cannot be classed as an economic success and its value as a public venture may be negative. In such a case, may not the expenditure of public funds on such works be criticized as of questionable propriety? Are there any important considerations other than an economic justification that may warrant the great outlay for such works?

It seems plain that engineers should never permit themselves to be lured from the true economic solution of such transportation problems by the blandishment of local commercial organizations which sometimes desire large sums to be spent in their localities with only a minor regard for the National service or the economic success of the project; nor should engineers permit themselves to be misled by glittering speculative estimates of future traffic that a more careful study would show could never develop.

The supreme test of the public value of any inland waterway must always be an economic one. Can the actual ton-mile cost to the shipper of hauling by barge and towboat, or by other similar means, when added to the ton-mile cost of interest on the first cost, depreciation, and maintenance of the waterway now borne by public taxation, effect, when combined, a saving over other means of transportation? How many of the inland streams, on which extensive navigation projects have been built, can now meet this test?

The low credit of the railways and the resulting cramping of their development of late years by the present public policies, may have a serious effect in the future, when a new prosperity shall follow the present depression. When that time comes, many years and much money may be necessary before the companies can replace their railways on a basis sufficiently broad to handle the volume of traffic presented. At that time, water transportation may perhaps be considered, to supplement other methods, and many of the waterways may then arrive at a new prosperity and public usefulness. How permanent and extensive this might become is, of course, subject to the usual economic laws from which there is no escape.

L. M. Adams,* M. Am. Soc. C. E. (by letter).—The author's interesting paper can be read with great profit by any one who may have similar works to build in a river subject to sudden and irregular flood stages, such as the Ohio.

It was the writer's good fortune to have considerable to do with the design of the later locks and dams on the Ohio River, and it is his recollection that the controlling idea in adopting the Chanoine type of movable dam for the Ohio River System was on account of the peculiar method, so much in vogue, of making up, during ordinary river stages, great fleets of loaded coal boats, which moved down stream on subsequent rises of the river. These fleets were so large that the stern-wheel towboat which controlled them, could do no more than steer the floating raft and, where conditions warranted, return to the Pittsburgh Coal District with the empty barges many weeks later.

* Maj., Corps of Engrs., U. S. A., Galveston, Tex.

The custom had become established of handling fleets of barges in this manner and the mere suggestion of placing fixed dams in the river, which would require the fleets to be broken up to pass through the locks, brought violent opposition which could not be overlooked.

As practically all the tonnage movement was down stream before and during the period the movable type of dam was adopted, the question arose at the time, whether it would not be more desirable to build fixed dams of comparatively low lift, say, 6 ft., with the idea that during fair sized floods these low fixed dams would be drowned and the coal fleets could pass down the river in the accustomed manner, special care being used not to start until the disturbance at the dams had become a safe minimum. However, the necessity of slightly increasing the flood heights with consequent complaints and claims from riparians, and the determined opposition of those who navigated the river, resulted in the abandonment of the idea of the fixed dam and the acceptance of the movable dam in lieu thereof, in spite of its enormous first cost and large cost of operation. Thanks to the long experience of the French in successfully operating movable dams and the valuable experience gained in building and operating several similar dams of earlier date along the Ohio River, it was not a difficult matter to design movable dams of unprecedented height and length. Many interesting features arose during the two years occupied in designing the new system, such as whether transverse rolling gates should be used instead of the more common mitered gates; whether the dams should be built on piling, or excavation be continued to bed-rock at somewhat greater expense; whether the dam foundation should be built solid or be of cellular construction; whether it was desirable to install water turbines in the structure or to take advantage of the low-head power within reach when the dam was up; whether to use the expensive bear-trap weirs, in addition to the long sections of Chanoine weir at each site; and, finally, whether fixed dams of considerable length could not be advantageously used at some of the sites, particularly in the lower river where the fall was slight, the river wide, and ample notice of approaching floods was always available.

It so happened that one of the early dams to be considered was Dam No. 48, below Evansville, Ind. It was evident from a study of the survey of the river that the situation here was different from that several hundred miles farther up stream. Unless the plans were afterward changed for other good reasons, Dam No. 48 contained the innovation of omitting the pair of standard bear-trap weirs. On the Lower Ohio River, there is always sufficient warning of the approach of floods, to afford ample time to lower the Chanoine weir, thus offsetting the great advantage of the bear-trap type of weir, namely, speed and power operation. Furthermore, a decided saving in the cost of the dam and in the time required for construction appeared possible by the omission of the bear-traps. The width of the river at this site was so great that if a standard type of construction, like that in the upper river, had been followed, it would have meant the building of a 700-ft. navigable pass, two standard 91-ft. bear-trap weirs, and 1 400 ft. more of expensive

Chanoine weir. It seemed desirable to reduce the length of weir, and calculations were made with that object in view. The discharge of the Ohio at low-water elevation, at Dam No. 48, was computed to be 7 160 cu. ft. per sec.; at the 7-ft. stage on the navigable pass sill, the discharge became 26 000 cu. ft. per sec.; and at the 9½-ft. stage above the navigable pass sill, which corresponded to a 7-ft. stage above low water, the discharge became 48 000 cu. ft. per sec. As is well known, the discharge for certain stages is greater on a rising than on a falling river. Careful inquiry was made among the lockmasters in the Wheeling District and in the Pittsburgh District to ascertain at what maximum stage of the river, the typical Chanoine wickets of the pass could be raised with certainty. It became apparent that there would be no detriment to navigation, if, on a falling river, the stage was allowed to fall somewhat below 9 ft., as all the larger barges (known as "boats") would have passed down before this, and the raising of the dam could be safely delayed until the stage had fallen to 7 ft. above low water. Therefore, it was concluded in the design of Dam No. 48, that:

First.—It was unnecessary to arrange pass and weir so that the pass could be raised on greater stages than about 9½ ft. over the pass sill or 7 ft. above low-water gauge.

Second.—It would be possible to raise the pass wickets against a head of 5 ft. and this would mean that the final closure of the pass at the 7-ft. stage of the falling river would be made with the upper pool about 13½ ft. above the pass sill and the lower pool about 8½ ft. above this same level.

With the weir at Dam No. 48 designed to pass the discharge of a 7-ft. stage of 48 000 cu. ft. per sec., with the upper pool at 13½ ft. above the sill, any delay in closing off the pass could not result seriously, as the difference between pool elevations would not then increase above the allowable 5 ft., and, as a matter of fact, the lower pool under such condition would begin to re-approach the 7-ft. stage and the head to decrease slightly and this again would cause a slight rise in the upper pool until equilibrium was established. By calculation, it was found that when the upper pool was at 13½ ft. above the pass sill and the lower pool at 8½ ft. above the same point and the river was falling, each foot of navigable pass would discharge about 125 cu. ft. per sec., each foot of Chanoine weir would discharge about 80 cu. ft. per sec., and each foot of the bear-trap weirs, if installed, would discharge about 120 cu. ft. per sec., these figures neglecting velocity of approach and end construction. It then became a simple matter to determine the length of Chanoine weir necessary to discharge 48 000 cu. ft. per sec. Neglecting the 2 000 cu. ft. per sec. as the minimum escaping between the pass wickets, it appears that 600 ft. of standard Chanoine weir should suffice to prevent the head against the pass wickets from rising above 5 ft. on finally closing. If it had been desired to introduce two standard bear-trap weirs in this work, they would have provided about 19 600 cu. ft. per sec. in themselves, and the length of Chanoine weir necessary would have become about 355 ft. As, at that date, two bear-trap weirs, with piers and piping, were estimated to cost $180 000 and the equivalent length of Chanoine weir, 245 ft., with two piers,

would cost only $110 000, a saving of about $70 000 seemed possible by omitting the bear-trap type from this design, the dam to be operated exactly as is done with similar movable dams on the Kanawha River, where success has been attained without the installation of the costly bear-trap weirs. Low-water discharge of the Ohio River at Dam No. 48 was calculated to be 7 160 cu. ft. per sec. Taking 600 ft. as the calculated necessary length of Chanoine weir—no bear-trap weirs to be used—it is found that the remainder of the river can be closed off with a fixed dam of a length of 890 ft., and that its crest can be fixed at 2 ft. below normal upper-pool level. This lowered elevation of the crest of this fixed dam section is such that the ordinary summer and fall discharge will suffice to maintain a full upper pool. However, a design to admit of flash-boards was provided for use under exceptional circumstances of extreme low water. It was also assumed that, at low-water discharge, openings between the pass and weir wickets might be closed with 4 by 4-in. timbers, called "needles". However, to be on the side of safety, it was assumed that there would still be a 1-in. strip of leakage space left between each pair of pass and weir wickets. This assumption gives a low-water loss through the pass of 2 100 cu. ft. per sec., and a similar leakage loss through the Chanoine weir of 1 230 cu. ft. per sec., or a total leakage loss of 3 330 cu. ft. per sec. The remainder of the low-water discharge of 3 770 cu. ft. per sec. would hardly suffice to maintain a full upper pool over the spillway of the fixed dam, but when this unusual condition arose, the flash-boards could be used. The gauge records showed that it would not be necessary to use the flash-boards more than about once in three years.

Further calculations were necessary to determine the maximum discharge that could be passed before it would become necessary to drop the pass wickets. It was assumed that the dam would be lowered when the upper pool rose to a point 6 in. above the tops of the pass wickets when standing. This pool level would give a depth of 11.5 ft. above the Chanoine weir sill and 15.9 ft. above the pass sill. Assuming the accepted design to include 600 ft. of standard Chanoine weir, 800 ft. of navigable pass, and 890 ft. of fixed dam, with crest 2 ft. below normal upper pool, calculation showed that the leakage through the pass wickets amounted to 5 000 cu. ft. per sec. and the 6 in. over the pass crest carried 800 cu. ft. per sec., the 600-ft. weir discharged 61 800 cu. ft. per sec., and the 2½ ft. over the fixed dam spillway carried off 11 000 cu. ft. per sec., or a total discharge of 78 600 cu. ft. per sec. passed the site, which corresponded to an open-river stage of more than 9 ft. above low-water level. This being the condition for which the test calculations were being made, the design seemed satisfactory as it would permit ordinary rises—to somewhat above 9 ft.—to be passed without throwing the main part of the dam and losing the pool. This feature becomes important when one considers what it means to dams farther down stream to be suddenly deluged by the great volume of water released, and also one must consider the many tributaries of the Ohio, which frequently have local rain storms and furnish small floods in themselves, which could be taken care of at the dams on the Ohio without losing the upper pool.

Mr. Hall's suggestion of giving to certain railroads, crossing the Ohio River, the exclusive privilege of operating feeder barge lines on the river, might show up well for the railroad tonnage for the particular road involved and might make the river busier, but it would justly arouse strong opposition from the competing railroads, and would introduce a new element in the rate situation under the supervision of the Interstate Commerce Commission, which rate situation already is sufficiently complicated.

Mr. Hall's statement that "Unfortunately, neither the Engineer Department, nor other Government agency, manages or seriously concerns itself with any part of the transportation problem other than the preparation of a sufficient waterway", is open to discussion. Before Congress adopts any river and harbor project, such as the canalization of the Ohio, elaborate preliminary examination and survey reports are made to cover in detail every phase such as "what is desired by local interests", "proposed plans to carry out the improvement", full investigation of "terminal facilities", the "local co-operation" offered, financial or otherwise, full "commercial statistics" of the locality, "local benefits" to be expected, and "general or national benefits" to be expected. These reports by District Engineers pass the Division Engineer and the Board of Engineers for Rivers and Harbors, each of whom makes full analyses of the District Officers' reports, visits the locality, holding necessary public hearings, and, finally, the reports pass the Chief of Engineers, U. S. A., who makes his own review and transmits the data through the Secretary of War to the proper committee in Congress, with definite recommendations based on every phase of the transportation situation in the locality.

Recently, the Engineer Department transmitted to Congress a report of 2 400 pages, fully illustrated, with large detail maps, on "Water Terminal and Transfer Facilities" of the harbors of the United States. This is one of the most comprehensive documents ever published and shows what great importance is attached to the matter of terminals, as distinguished from the waterways leading to them. Similar elaborate investigations have been made of the rail facilities leading to the ports, the tributary territory, the terminal charges, etc.

The Interstate Commerce Commission is fully empowered to regulate interstate rates by water as well as by rail, and it frequently refuses to grant requests for reductions in rates, as well as increases. Here, seems to lie the agency for protection against "cut-throat" competition.

There is no doubt but that the Federal Government could force a greater use of its rivers by the grant of exclusive privileges, seizure or confiscation of certain rail lines, or arbitrary changes in freight rates, but it is hardly to be supposed that the situation warrants such action. There are many good reasons why, in the United States, commerce should be permitted to seek its own routes irrespective of whether the Federal Government has a substantial investment in waterways, some of which may not be making a satisfactory tonnage showing. What would the situation be if the waterways had been

improved at the expense of private capital, which always demands interest and return of the original investment? This problem looms large to the rail carriers and their security holders.

C. I. GRIMM,* ASSOC. M. AM. SOC. C. E. (by letter).—The author has discussed to a greater or less extent all the engineering features that pertain to the construction of locks and dams on the Ohio River, and particularly to Dam No. 18. This discussion, therefore, will be confined to elaboration on a few subjects which have been of interest to the writer in studying locations and preparing designs and estimates for a considerable number of locks and dams and which are covered rather briefly by the author. These subjects are: (*a*) Foundations; (*b*) weirs; and (*c*) lock-gates.

(*a*).—*Foundations.*—For the first thirty-one dams, it has generally been practicable to build on rock foundation, but below Dam No. 31, such foundations are exceptional. Where rock is not available, dams are supported on wooden piles, generally 30 ft. long, and the present practice is to place a row of interlocking steel sheet-piles, 40 ft. long, under the up-stream edge of the foundation. For the earlier dams, these sheet-piles are of wood, 25 ft. long, and of tongue-and-groove construction. When built on piles, the foundations are protected below the dam by a rock-filled timber crib and an apron of heavy rip-rap.

Although it might appear that for these low lifts, not exceeding 9 ft., the importance of a rock foundation is not significant, this is not true on account of the scour below the weir, which is so extensive that the stability of dams built on pile foundations is endangered to some extent, thus making it necessary to take soundings periodically and place additional rip-rap from time to time. This is especially true in the lower stretch of the river, where the underlying material is sand or contains a large percentage of sand. Where rock foundations have been found, the rock has generally been at such an elevation that the dams were constructed economically by excavating inside an open box coffer-dam, such as was used for Dam No. 18, and placing the concrete foundations on a cleared rock surface. Such construction has been carried to various depths up to a maximum of about 20 ft. below low water. If rock is at a depth of 20 ft. or more below low water, a pile foundation will cost less than one on rock. The advantages of building on rock, however, warrant some additional cost. It has not usually been necessary to give this matter careful consideration, because where the depth of rock was not less than 20 ft., it was so much in excess of this that the cost of building on it was readily seen to be excessive. In the case of Dam No. 32, which is now being designed, the depth of rock is about 23 ft. below low water, and plans for building this dam on rock are being considered. It is proposed to utilize a box coffer-dam of the usual type and inside of this coffer-dam to sink open concrete caissons from the river bed to rock, a distance of about 12 ft. These open caissons, which are comparatively small units, will then be pumped out one at a time and filled with concrete. It is estimated that this construction will cost little more than a pile foundation. At Dam No. 23, where the under-

* Asst. Engr., U. S. Engr. Office, Cincinnati, Ohio.

lying rock was about 15 ft. below low water, the Dravo Contracting Company constructed the dam (840 ft. long from the lock to the bear-trap) inside of coffer-dams about 45 ft. wide and 160 ft. long, the walls being of a single row of Lackawanna steel piling braced across the 45-ft. width. This work was accomplished speedily and economically.

Ohio River dams constructed on sand and gravel, with a cut-off wall of 40-ft. interlocking steel piles, have a length of "creep" equal to about ten times the maximum head, and where 25-ft. wooden piles are used, it is about eight times the maximum head. Experience has shown that in practice the wooden sheet-piles, even though carefully driven, are not sufficiently tight to form an effective cut-off. Their use has been limited to the upper part of the river where foundations consist of rather coarse gravel and sand, and they are not regarded as adequate for the more sandy foundations of the lower river. No evidence of "boils" under any dams that are in service has appeared, and it is believed that these dams have adequate protection from this danger, unless they are undermined by scouring action below the weirs, which action must be carefully guarded against by proper construction and periodical inspection.

(*b*).—*Weirs.*—The weirs for Dam No. 18 and the earlier Ohio River dams were designed to pass a flow equal to the open-river flow at a stage of from 9 to 10 ft. The apparent advantage of having a large weir capacity is that it lessens the extent of maneuvering the wickets of the navigable pass, but this is an advantage only in case the weir can be maneuvered with greater ease or greater speed than the navigable pass. However, in practice, no more suitable means of raising the wickets of the weir has developed than the maneuver boat. Discharges equal to a 12-ft. stage are passed through the weir and a part of the lowered dam, since the dams are partly raised at stages greater than 9 ft. and are not entirely lowered when the capacity of the weir is reached, unless it is evident that the approaching rise will be high enough to submerge the pass wickets the tops of which are generally about 13 ft. above low water. In practice, a part of the navigable pass, therefore, is used as a weir and the capacity of the weir including the lowered part of the navigable pass is equal to an open-river stage of about 12 ft. As stated by the author, the operation of the Chanoine weir from the service bridge has generally been discontinued, and on account of their inaccessibility to the maneuver boat which operates the movable dam, these weirs are not used. Many of the dams now in operation have, therefore, a usable weir of two 91-ft. bear-traps only. At Dam No. 29, for example, the capacity of the bear-traps is about equal to a 7-ft. open-river stage. This dam is maneuvered successfully to pass any stage up to 12 ft., by lowering a part of the navigable pass. It is necessary, of course, to raise the pass wickets against greater heads than would prevail if the Chanoine weir was in use, and it is rather difficult to raise the last wickets of the pass. In view of the foregoing, it is not regarded as necessary to provide, in addition to the navigable pass, a weir capacity sufficient to discharge a 9-ft. open-river flow and as the cost of the dam is decreased by decreasing the length of the weir, this factor should be given proper weight in the design of weirs.

The bear-trap is generally recognized by those who have had experience on the Ohio River, as the most satisfactory regulating weir that has been devised for this stream, by reason of the fact that it may be operated with greater ease, greater safety, greater speed, and more certainty than any other type. However, in determining the extent of its use, consideration must be given to its first cost, which is high in comparison with that of wicket weirs. Two 91-ft. bear-traps with their piers occupy 220 lin. ft. of dam and will cost more than double the same length of wicket weir. The cost per foot of a weir of Chanoine or Bebout wickets is considerably more than that of a fixed dam, and where a part of this weir may be replaced by a fixed dam, by using some of the navigable pass as a regulating weir, a saving in cost will be effected. Economic considerations, therefore, should limit the weir lengths to those required by the following conditions:

(1) There must be a sufficient area of movable dam and weir so that, when they are lowered, the velocity in the contracted channel will not interfere with navigation.

(2) The weir area must be sufficient so that the pass wickets need not be maneuvered against a head greater than 5 ft.

In the recent designs for Dams Nos. 34, 36, and 38, the weirs have been given considerable attention, and the completed plans have some features which differ from Dam No. 18, or any other Ohio River dams. In these designs, two 91-ft. bear-traps, with the sill 15 ft. below the upper pool, are provided and also a weir, 100 ft. long, of Chanoine wickets, with the sill 11 ft. below the upper pool. The Chanoine weir is provided with a tripping bar for lowering, and this weir is placed between the bear-trap and the navigable pass so that it may be maneuvered by the boat which maneuvers the navigable pass, as the weir wickets will be raised by the maneuver boat. The tripping device is similar to that which has been in successful operation on weirs of the Big Sandy River and the mechanism for operating the tripping bar is on the bear-trap pier.

The weirs for these dams, exclusive of the navigable pass, will discharge a quantity about equal to an 8-ft. open-river stage when pools are at normal height above the dams. The height of the upper pool above low water is as follows: Dam No. 34, 13 ft.; Dam No. 36, 13.7 ft.; and Dam No. 38, 11.6 ft. As the discharge through the weirs will raise the water below to an 8-ft. stage, the maximum heads on the pass wickets, when the weirs are open and the upper pools normal, will be as follows, without allowance for leakage between the pass wickets: Dam No. 34, 5 ft.; Dam No. 36, 5.7 ft.; and Dam No. 38, 3.6 ft. The leakage between the pass wickets will further reduce this head, as will also the raising of the dams below. Furthermore, the raising of the pass wickets is usually completed before the upper pool has filled, although this does not apply when raising only a part of the dam that has been lowered to pass a discharge slightly greater than the weir can pass. In view of these considerations, it appears that the pass wickets, which are used for pool regulation at these dams, will usually be maneuvered against heads of less than 5 ft. and that a weir capacity equal to an 8-ft. open-river

discharge is ample for these dams. The space between the bear-trap and the abutment is closed, by a fixed concrete dam having a minimum length of 252 ft. at Dam No. 36. This places the weirs far enough from the bank that no appreciable scouring of the bank is anticipated. On account of the severe scouring action that occurs below the bear-traps, they should be placed some distance from the river bank if the width of the river at the dam permits it.

(*c*).—*Lock-Gates.*—The lock-gates of Dam No. 18 and of all other Ohio River locks constructed prior to 1916, are of the rolling type. These gates move from recesses back of the land wall across the lock chamber, closing the ends of the locks and forming a water-tight bulkhead. The gate at the upper end of the lock is 17.4 ft. high and that at the lower end 22 ft. high, or somewhat less, depending on the lift. Each gate is mounted on ten pairs of standard car wheels which roll on a steel track.

This type of gate, although somewhat unusual, was selected on account of the limited height of the gates and the great width of the lock, which are far from ideal conditions for the more usual type of mitering gates. The rolling gates, although they have occasioned some minor difficulty from broken wheels and tracks, in general, have operated satisfactorily in the upper river. In the lower river, however, where deposits of mud and sand are extensive during high water, the recesses, unless closely sealed, become so filled with deposits that the cleaning of them involves considerable expense as well as possible interruption to navigation before the lock can be placed in operation. In view of the difficulty and uncertainty of sealing the recesses, the rolling gates were not regarded as satisfactory for the lower river and, in 1914, the Ohio River Board of Engineer Officers adopted a design for mitering gates. As previously stated, the great width of the lock and the limited height of the gates are conditions which are not favorable for mitering gates, but by the use of vertically framed gates, well braced, and with strong bearings and anchorages, a satisfactory design has been effected. These gates have been installed at ten locks and, except for a few minor defects in details, which were readily corrected, have operated satisfactorily, and have been found readily adjustable for any wear, deflection, or warping that has occurred. The recesses for the rolling gates are readily coffered by means of a timber bulkhead and pumped out when repairs or painting is necessary, whereas, for the mitering gates, it is either necessary to install a considerable coffer-dam and pump out the lock, or to lift the gates out by derrick boats. It appears that, in the case of the mitering gates, the latter method and the carrying of spare gates will become necessary if navigation becomes so extensive that it cannot be interrupted except for short periods.

Considerable study has been given to the comparison of first cost of Ohio River locks with rolling or mitering gates, and it has been found that, in general, neither has any marked advantage in this respect when operating machinery and power plant are considered. If the lock is located at a steep rocky bank, the rolling gates are at a disadvantage as it is either necessary to make costly excavation for the recesses or to move the lock out from the bank and this increases the cost on account of the filling and paving required back of the land wall. Except for special cases, the first cost is not a con-

sideration and the advantages of operation, making repairs, replacements, etc., although somewhat balanced for present conditions, would be in favor of mitering gates, if navigation becomes as extensive as is contemplated and hoped for when the improvement of the river is completed.

B. F. THOMAS,* M. AM. SOC. C. E. (by letter).—In recent study of the design of dams on the Ohio River, in the vicinity of Cincinnati, Ohio, considerable discussion has arisen as to several points on which no great emphasis (at least in print) has heretofore been placed. Some of these points will be enumerated by the writer in this discussion. The dams have generally been provided with two bear-trap weirs, a pier separating the first trap (counting from the lock) from the navigation pass. The pass, which is closed by Chanoine wickets, is usually 700 ft. wide, and the width of each bear-trap is 91 ft. Following the bear-traps, there has been provided, at a number of dams, a weir of Chanoine wickets with a sill considerably higher than that of the pass. In recent discussions, it has been suggested that the Chanoine weir be placed next to the pass and that there be no pier to mark the change in sill elevation. It has also been proposed to lower the weir wickets with a tripping bar similar to the method used on Big Sandy River, and on the twenty-seven dams of the Belgian Meuse, the maneuver boat to be used only for raising this section of the dam, but to be used both in raising and lowering the pass wickets, as at present.

The writer would recommend for dams on this part of the Ohio River, the following arrangement: Chanoine wicket pass, 700 ft. long; pier, 12 ft. wide; two bear-traps, each 91 ft. wide; pier, 12 ft. wide between traps; and fixed weir, 181 ft. long, or sufficient to reach the shore abutment.

In case greater weir capacity is desirable, or necessary, he would recommend that a Chanoine wicket weir with tripping bar be placed next the pass, with the pier between it and the pass, the length of the fixed weir being reduced accordingly. Although he does not consider a pier at the end of the pass an absolute necessity, in case a Chanoine weir with a sill considerably higher than that of pass is put in, still it is a desirable arrangement, and it is believed that there is practical unanimity among navigators and river men in general that such a guide for their movement at dams should be provided. The currents are uncertain at the dams and a tow is liable to be carried against the weir and wrecked. The use of a buoy or especially constructed wicket for defining the point of change in elevation of the sill, it is believed, would be unsatisfactory; in fact, it is not believed that a buoy could be maintained in periods of drift and ice.

It is believed that with a sill about 4 ft. higher than that of the pass, little, if any, trouble from gravel interfering with the tripping bar, would be experienced. However, its mechanism and the bar itself should be designed with sufficient strength and power to crush such obstruction to the movement of the bar as might interfere therewith. The fact that at the time the bar is in use, the water is surging at great velocity through the spaces made by the falling wickets would insure, it is thought, the cleaning of the deposit from around it.

* Mr. Thomas, who was U. S. Asst. Engr. at Huntington, W. Va., died on April 14, 1923.

From experience at one dam in the upper river, which has no bear-trap, and from similar experience at dams having only one bear-trap, as reported by the engineer in charge, it would seem unwise to build a new dam with only one trap. The regulation of pool levels where navigation exists is a most important feature in the Ohio River System, and it has been proven that no other device thus far tried or proposed will equal the bear-trap as a regulator. With it, regulation is certain, operation easy and speedy, action reliable, and its work is generally satisfactory; its upkeep is not expensive, and will become less as its working becomes better understood by the engineers in charge.

After much study the writer has come to the conclusion that it would be a serious mistake to substitute any kind of weir heretofore proposed for the bear-trap. The following memoranda are submitted for consideration. As to a pier between a pass and a bear-trap or between a pass and a weir of any type:

(*a*).—The junction of the two sills at different elevations would without a pier form an obstruction to navigation, which cannot be seen by day nor lighted at night.

(*b*).—It furnishes a convenient and firm mooring for the maneuver boat and its lines, during maneuvers, and if its up-stream end is placed flush with the up-stream face of the wickets, it would offer no impediment to the movement of the boat.

(*c*).—It is a guide to navigation; without it, the cross-currents may cause a tow to swing over against it at stages when the weir sill would have insufficient depth for tow.

(*d*).—Navigation has always had this sort of guide to the passage of the dam and would, it is believed, complain greatly and feel uncertain without it.

(*e*).—The experience of the engineers in the Wheeling District indicates that where there are two traps, the maneuver boat was sent out for regulating purposes only five times in a season, while with one trap it went out thirty-six times, and with no trap eighty-nine times. This seems a most convincing argument in favor of two bear-traps. With the large number of tributaries coming in below the dams in the Wheeling District, the writer believes it would be very unwise to put in a dam with less than two traps, especially as the quantity of drift and number of quick, unannounced freshets are great.

MALCOLM ELLIOTT,* M. AM. SOC. C. E. (by letter).—Although the time has not yet arrived for a definite decision as to whether the improvements of the Ohio River and their large cost have been justified to the taxpayers, it would seem to be proper, in discussing this paper, to survey the accomplishments to date, the status of water transportation on the Ohio River, the cost of the work, and the prospects for the future.

Thirty-six of the Ohio River dams are now ready for operation. The series is complete from Nos. 1 to 26, inclusive, Dam No. 26 being just below Point Pleasant, W. Va. (Fig. 1). Dam No. 27 is about 80% completed and will be

* Maj., Corps of Engrs., U. S. A., Fort Humphreys, Va.

ready for operation during the season of 1923, making the series complete from Nos. 1 to 29, inclusive. Below Dam No. 29, Dams Nos. 31, 33, 35, 37, 39, 41, 43, and 48 are in operation, thus making it possible to fill every alternate pool as far as Dam No. 43, and greatly improving the condition over the open channel as it existed before the construction of the dams. All the even numbered dams intervening, to include Dam No. 44, are under construction, and their completion may be expected within a reasonable time, thus furnishing slack-water navigation from Pittsburgh, Pa., to Leavenworth, Ind., a distance of about 650 miles—the upper two-thirds of the length of the river. Dam No. 48 is the only one below Leavenworth ready for operation.

Below Leavenworth, the river conditions become less favorable to the construction of locks and dams. The bottom is less stable than in the upper reaches, and it is feared that much trouble will be had with deposits of sand, which will make difficult the operation of the dams and lock-gates. The abandonment of the slack-water system in favor of open-channel regulation by dredging and training works in the lower part of the river, has been considered, but it is not known whether any decision has been reached. A little experience at Dam No. 48, near Evansville, Ind., recently completed, will furnish information as to the feasibility of constructing more locks and dams in that section of the river.

The author gives the tonnage for 1894, 1916, and 1917 only. To supplement these figures, it may be said that the greatest tonnage in any year was 14 054 000 in 1900, the smallest, since 1892, was 4 599 000 in 1917, and the tonnage for 1920, the last year reported, was 9 382 000, hauled an average distance of 126 miles, making 1 184 000 000 ton-miles. It will be noted that the greatest tonnage was carried before the slack-water improvements were even begun and that now, with these improvements more than two-thirds completed, it is less than it was without the dams. Therefore, the question might well be asked, would it not have been better to have made no expenditures? This question and some of the factors which have influenced commerce on the Ohio River will be discussed subsequently. First, however, an estimate is given of the costs of the work to June 30, 1921, the latest date for which published figures are available.

The following figures are compiled from the report of the Chief of Engineers, U. S. Army, for the fiscal year ended June 30, 1921:

Total amount expended on new work on all projects to June 30, 1921, including the purchase of the Louisville and Portland Canal, improvements of Pittsburgh Harbor, snagging, and open-channel work	$85 746 412
Total amount expended on maintenance, operation, and care to June 30, 1921	13 268 705
Total of all money spent on Ohio River to June 30, 1921	$99 015 117
Expended for operating and care of locks and dams for year 1920-21	$1 061 973
Maintenance of dredging and snagging, year 1920-21	291 921
Total channel maintenance, operating, and care expense for year 1920-21	$1 353 894

The figures quoted represent only cash disbursements and include no allowance for interest or depreciation, except in so far as the depreciation has resulted in expenditures for renewals. Interest and depreciation should certainly be considered with the operating costs incurred by the Government and by the carrier in computing a financial summary of the operations of any waterway. Because the resulting balance sheet compares unfavorably with a similar statement for a railroad of like mileage, it does not necessarily follow that the waterway is a commercial failure. Its existence might be sufficiently beneficial to adjacent industries, development of territory, and increase of land values, to justify the enterprise, notwithstanding that it is supported in part by Government subsidies.

There is such variation in the length of service of the various parts of a movable dam that computing the proper allowance for depreciation to provide a sum for replacement would be difficult. Some of the wicket irons, for instance, have lasted only 5 or 6 years, whereas the concrete should last 100 years or more. As a sinking fund of $1 per year, if invested at 4%, will produce $100 in about 40 years, it is believed that an allowance of 1% of the total investment in new work, added to the actual expenditures for repairs and replacements included in the annual disbursements, would be a sufficient allowance for depreciation. This is equivalent to the assumption that with yearly repairs and renewals at the present rate, the structures will last for 40 years and that the project should be charged with a sufficient sinking fund to produce the money needed for their replacement at the end of that period. The interest on the capital invested may fairly be assumed at 4% of the expenditures for new work.

With these assumptions, the total annual charges may be estimated roughly, as follows:

Total capital invested to date, about		$100 000 000
New capital needed to finish project		20 000 000
Total eventual cost of project		$120 000 000
Interest and replacement at 5% per year		$6 000 000
Operating expenses, 1921 (thirty-five dams)	$1 062 000	
Operating expenses after project has been completed (fifty dams)	$1 062 000 ÷ 0.7 =	1 500 000
Channel maintenance, dredging, etc		300 000
Total yearly maintenance, operating and care charges, interest, and depreciation		$7 800 000

These figures, although approximate, are probably more accurate than any estimate that can be made of the volume of traffic that will be moved through the agency of these expenditures. If the benefits are to be computed by comparing the present traffic with that prior to the construction of the improvements, then such benefits are nil, because the traffic now is less than before. It is known that such a pessimistic view of the value of the improvements is not justified, because, as will be shown later, events which have no relation whatever

to the river and which could hardly have been foreseen when the project was adopted, have resulted in a large decrease in the river traffic; and without the present facilities the decrease in traffic would have been much more than it has actually been. The benefit to date, therefore, is not measured by the increase in total traffic since the improvements were installed, but by the increase in traffic over what it would have been without the improvements.

At the time the Ohio River improvements now in progress were planned, there existed a large down-stream movement of coal—more than 1 000 000 tons annually—from Pittsburgh, Pa., to Cairo, Ill., and several million tons from Pittsburgh to Louisville, Ky., and intermediate cities. At that time, there was no reason to suppose that this traffic would not continue and, in fact, increase considerably, if channel conditions were improved. This traffic from Pittsburgh to lower river points, however, has almost disappeared. During 1920, for instance, only nineteen coal barges passed Lock No. 13, near Wheeling, W. Va. The abrupt termination of the coal traffic from Pittsburgh was not due to the cost of moving the coal by water, which is, and always has been, less than by rail. Reliable information obtained by the writer, from cost records of a company engaged in transporting coal by water during 1921, indicates the cost to the carrier for a 250-mile haul to be not more than 5 mills per ton-mile, including the short haul by rail from the mine to the tipple, loading, towing loaded barges down stream and empties up stream, overhead, interest, and depreciation. Railroad rates for coal during 1920 were from 7.1 to 14.6 mills per ton-mile for a similar distance. Therefore, the disappearance of the commerce in Pittsburgh coal is not due to the ability of the railroads to haul it at less cost than by water. The general tendency for industries to use coal procured from local sources, thus avoiding the cost of long hauls, is to be recognized in considering this decrease in traffic. A particular instance, having direct bearing on this traffic in Pittsburgh coal, is the greatly increased need for coal in the Pittsburgh District, following its large industrial growth in recent years, especially during the World War, resulting in the local use of a part, at least, of the surplus which in former years went down the river in barges. It is possible, also, that new markets, remote from the river, to which the coal is hauled by rail, have been developed in recent years.

It is difficult to estimate how much traffic has disappeared from the river from the causes named, but an examination of detailed records of tonnage prior to 1912, shows that the average commerce was 10 334 000 tons per year and that with the Pittsburgh coal traffic eliminated, there remained about 6 500 000 tons. The commerce for 1920 was 9 382 000 tons, an increase of nearly 50% in the traffic other than Pittsburgh coal, part of which increase was made possible by the expenditure for improvements. The statistics for 1920 show that there was a traffic of 417 129 000 ton-miles through the locks. If this traffic had been compelled to pay tolls equalling the yearly cost of maintenance, depreciation, and interest charges, about $5 600 000 in 1921, the tolls would have amounted to 13.4 mills per ton-mile. Adding this to the carrier's costs of, say, 5 mills per ton-mile, the total cost of moving the freight would have been about 18.4 mills per ton-mile, as against the prevailing railroad rates for a similar distance (126 miles), of from 12.5 to 13.9 mills per ton-mile.

Such a comparison, however, is not fair to the waterway. One should stop to consider that the project is incomplete; that the outlet by water to the markets beyond the Ohio River is no better than it was before the present project was commenced; that the railroads have built paralleling lines and are allowed to establish lower rates to meet water competition; that there is practically no co-operation between rail and water routes; that railroads charge more for hauling inland the freight from the river than that from other railroads; and that until these disadvantages are overcome, the capital for suitable floating plant, terminal, and transfer facilities cannot be found, and the water transportation companies must labor under the disadvantage of using improper equipment.

Railroads provide branches and sidings so as to connect the source of production with the warehouse of the jobber or consumer, but waterways cannot do this and thus cannot reach their full usefulness except by co-operation with the railroads. This co-operation should include mutual arrangements for shipping goods by rail and water combined, the acceptance by both rail and water carriers of goods for shipment over both routes on through bills of lading, equitable distribution of the through freight revenue between the rail and water carriers, and the provision of convenient terminal and transfer facilities and appliances for transshipment of the freight. There is little, if any, such co-operation on the Ohio River. In its place, there are artificial barriers which must be overcome before the river will amount to anything.

According to the report of the Chief of Engineers for 1921 (Part 2, page 22), railroad rates for similar distances are from 10 to 20% lower when there is water competition than elsewhere. The discrimination against river freight is shown also by the following example: The rate on coal in carloads from Charleston, W. Va., to Indianapolis, Ind., is $2.80 per ton, *via* the Chesapeake and Ohio Railroad, to Cincinnati, Ohio, thence, *via* the "Big Four" to Indianapolis, of which amount the "Big Four" receives $0.91 per ton for its share of the haul, whereas coal brought from Charleston to Cincinnati by boat, then loaded in cars by the shipper, and turned over to the "Big Four", is charged $1.15 per ton for the same haul from Cincinnati to Indianapolis.

Thus, the railroads discriminate against river coal and cause the water carrier to overcome an artificial disadvantage, in this instance, of $0.24 per ton. The effect of such discrimination is to limit the market for river freight to the communities on the river banks.

As long as these artificial and discriminatory barriers exist, the gaining of profits by water carriers is so uncertain that the navigation interests will continue to suffer the disadvantages due to the use of antiquated and improper equipment, because of difficulty in raising capital, and the shippers, being compelled to pay the extra cost of this inefficient service, will be deprived of the benefits which otherwise would be obtained from the waterway.

The Ohio River is favorably situated for commerce. At its upper end, it terminates in the remarkable industrial area and region of mineral resources centering around Pittsburgh. At its lower end, it terminates in the Mississippi River which affords dependable, all-year navigation, either to the Gulf or

to St. Louis, Mo., the former a distributing point for export business, the latter a gateway to the Middle West. Intermediate points along the Ohio River are such cities as Wheeling, producing coal, oil, and steel manufactures; Cincinnati, a manufacturing city and distributing point for other important manufacturing towns; and Louisville, a jobbing center for Kentucky, Tennessee, Alabama, and other States in the South. The Ohio River is fed below Pittsburgh by the Kanawha River, now shipping more than 1 000 000 tons of coal per year and capable of much larger production; the Muskingum River with its head of navigation at the important manufacturing city of Zanesville, Ohio; the Green River, penetrating to the center of the oil and coal-producing section of Kentucky; and the Cumberland and Tennessee Rivers communicating with Nashville and Chattanooga, Tenn. Reaching these important regions and cities, there can be little doubt that the Ohio River and its tributaries are situated so as to carry a large volume of traffic, if only the navigable depths are provided and artificial restrictions removed.

An instance of what can be done with water transportation on inland rivers, is seen in the operations of the Mississippi-Warrior Service. This service has arrangements with the railroads, whereby through shipments, part rail and part water, can be made on through bills of lading. It has modern boats and barges and is constructing efficient terminal and transfer facilities. After operating more than two years at a deficit, it began to earn profits on its Mississippi business, as the tonnage increased during the last three months of the fiscal year ending June 30th, 1921. In this period and the two months following, although the fleets operated at only part capacity and were served by unfinished terminals, the service earned a profit of about $98 000 after meeting all operating expenses and depreciation charges based on the high prices paid for the equipment during and shortly after the World War. The freight rates were from 5½ to 40 cents per 100 lb. lower than all-rail rates for similar distances.

The Ohio River can be made navigable at less cost than the Mississippi; it is situated equally favorably for prospective business; and it, also, can be made into a profitable enterprise if a dependable channel is provided throughout its length and the existing discriminations are removed.

As the author states, an agency is required, the duty of which will be to manage the water-transportation problem other than the preparation of the waterway, but, in his statement that no such agency has been created, it is believed that he has overlooked the Inland and Coastwise Waterways Service, established by Act of Congress during the war, in order to supplement the greatly overloaded railroad systems. This agency is now functioning, and through one of its departments has built up the important Mississippi-Warrior Service mentioned previously. With proper support and sufficient appropriations, this agency should be in a position to foster the growth of the river-transportation business and promote the use of waterways for which many millions have been spent in channel improvements, but it can do little in promoting Ohio River commerce until the lower reaches have been made navigable so as to afford connection with the Mississippi River.

FREDERICK B. DUIS,* M. AM. SOC. C. E. (by letter).—For some years, the writer has been connected with the construction and operation of Ohio River locks and dams in the U. S. Engineer District, Wheeling, W. Va., and, since 1915, Lock and Dam No. 18 to which the author's paper especially relates, has been included in the works under his charge. This discussion is based largely on information gained through experience in maintaining and operating these works.

Attention is invited to some apparent errors in the last paragraph of the historical data under the heading, "Introduction". The locks and dams to Dam No. 39 are stated to have been constructed, but Dams Nos. 25, 27, 30, 32, 34, 36, 38, and 39, at the probable time of the preparation of the paper, were not completed, although Dams Nos. 25 and 39 were nearly so and were expected to be ready for operation at the commencement of the low-water season of 1922. Dams Nos. 41, 43, 44, 45, and 48 are stated to have been placed under construction, but Dams Nos. 41, 43, and 48 were completed and placed in operation in 1921, Dam No. 48, late in the year. At the end of 1921, there were thirty-four Ohio River locks and dams in operation.

Table 2 gives the commerce carried on the Ohio River during 1894, 1916, and 1917. With the statement following this table, those figures indicate (although perhaps not so intended) a gradual decline of the commerce on the stream, in spite of the large expenditure for the construction of locks and dams. The facts are that the decrease in the commerce did not commence in 1894, nor has it continued to date. Reference to the reports of the Chief of Engineers, U. S. Army, will show that from 1894 to 1905 there was an average, although not a regular, increase, the commerce in 1905 amounting to more than 13 000 000 tons, of which about 3 700 000 tons were of coal from Pittsburgh to lower river points. From 1905, an average, but not a regular, decline in the traffic continued until 1917. By 1917, the coal traffic from the Pittsburgh territory to lower river points had practically ceased, the cause of which was in no way related to the river. The commerce previously cited for 1905 included that carried by ferries which, although not separately shown in the published report for that year, amounted to about 2 000 000 tons, as estimated from the amount of such traffic shown in later years when it was reported separately. The commerce given by the author for 1917 does not include the ferry traffic, so proper comparison with previous years when it was included requires that this class of traffic be omitted. Allowing for the 3 700 000 tons of coal carried in 1905, which traffic had ceased in 1917 for causes entirely foreign to the river, and also making allowance for the 2 000 000 tons estimated to have been carried by ferries in 1905 and not included in the author's figures for 1917, the actual decline in the commerce from 1905 to 1917, for which the cause may be attributed to the river, was approximately from 7 300 000 to 4 600 000 tons. Such were the conditions to 1917, but they did not so continue and, in the writer's opinion, the author has erred in not showing the commerce for the subsequent years as available from published reports, as the year 1917 was the turning point in the amount of commerce on the Ohio River and later data give a different aspect on the situation.

* Asst. Engr., U. S. Engr. Office, Huntington, W. Va.

In the published reports available, the commerce for the three years since 1917 is given as follows: 1918, 6 171 412 tons; 1919, 5 400 377 tons; and 1920, 9 382 463 tons. This shows an increase of nearly 100% from 1917 to 1920. The decrease in 1919 compared with 1918 was due to the temporary depression in the industrial activities during the early part of that year. The large increase in 1920 was influenced in the opposite direction by the industrial situation, but the amount of commerce carried in 1920 could not have been possible without the slack-water navigation then available. The question may be asked, why did the turning point in the amount of commerce occur about 1917, when the improvements had been under way for many years and a considerable number of the locks and dams had been in operation for some time? The answer is that not until about 1917 had the improvements progressed far enough to make them of practical benefit to navigation. In 1917, continuous slack-water navigation was made available from Pittsburgh to Dam No. 20, down stream 200 miles, and additional locks and dams providing intermittent pools were in operation from Dam No. 20 to Cincinnati. This practically insured a continuous navigable stage for craft of lighter draft, such as packet-boats, between Pittsburgh and Cincinnati. Craft requiring a greater depth of water than packet-boats could also operate over this section of the river with only infrequent suspensions on account of the river stages. It is, therefore, not a coincidence that, after 1917, the packet business which had almost disappeared from the upper part of the river, began to revive, as the result of the improvements. The foregoing data are in contradiction of the author's statement, in the paragraph on "Commerce", that he thinks the building of locks and dams is not rapidly increasing the tonnage and that under present methods of operation no company carrying passengers and freight in less than barge loads has built up a trade and held it at a fair and profitable rate. The carrying of freight in less than barge loads has revived to a considerable extent and, to the best of the writer's knowledge, at a profitable rate. If it had not, the parties engaged in this business would not be gradually expanding their facilities, as they have been doing, even through the recent period of the most severe industrial depression that has been experienced in the Upper Ohio Valley for many years.

A gradual increase in barge traffic, also, may be expected as industrial conditions improve, in fact, except for coal, it has been increasing in spite of the recent unfavorable conditions. One company, recently organized, has engaged in general towing in barge-load lots, considerable of its business consisting of the transferring of steel products from the Upper Ohio to Mississippi River points. The traffic manager of this company informed the writer that inquries for the services of the company were far more than its capacity to handle with its available plant, consisting of three towboats and a considerable number of barges. One steel company, in the Pittsburgh District, has also commenced transporting some of its products down the Ohio River with its own fleet.

The Ohio River Dam, selected by the author for description in his paper, was finished in 1910, and was the seventh to be completed, of the thirty-four that are now ready to operate. There are a number of items in its design and

arrangements that have been found unsatisfactory and are now obsolete, and the later dams have a number of improvements devised since Dam No. 18 was built. It seems proper to refer to these changes and show the reasons for them, in order that the latest practice in the design of such structures will be on record.

A movable dam is one the purpose of which is to pass high waters without appreciable increase of stage over natural stages, to allow open-river navigation when the open river has sufficient depth, and to increase the depth to a navigable stage during periods of low flow. To answer these purposes, the Ohio River dams have been provided with three principal elements: (1) the lock; (2) the navigable pass; and (3) the regulating weir.

Probably the most complicated of the operations on a movable dam are those connected with the regulation of the pools. The regulating weir is designed to pass water not needed for locking during periods of surplus, in such a way as to maintain a navigable depth in the pool above the dam. Its discharge capacity must be made variable by means of movable parts so as to correspond with the varying flow of the river. There are many conditions to meet, their relative importance is not seen the same by all designers, and the appliances have not always worked in the manner the designers thought they would. For these reasons, there has been a continual change in the design and layout of the regulating weirs since the Ohio River improvements began and, even now, the opinions of the designing engineers have not crystallized into a definite standard arrangement for this important element of a movable dam.

The author's Fig. 8 shows a photographic view of the completed Dam No. 18. The navigable pass is of the same design as that which has been in use on the Ohio for many years, and no further mention of it is necessary, except with reference to the statement made by the author that the pine timber used in the construction of the wickets in this dam is the best wood for the purpose. As observed from service, oak is so much superior to pine in resistance to decay and physical injury that the latter wood is not being used at the present time for such purpose. To the best of the writer's knowledge, the wickets at Dam No. 18 were the first on the Ohio River to be constructed of pine timber, and, a few years later, pine was used at Dams Nos. 20 and 26, but at all the other dams constructed before and since, on this river, oak timber has been used for that purpose, and has demonstrated its superiority.

Considerable difficulty is being experienced in regulating the discharge through Dam No. 18, on account of the inadequate capacity of the two small bear-traps and unsatisfactory operation of the Chanoine wicket weir. The total discharge area of the two bear-traps is 1 350 sq. ft., whereas at all the dams, except one, in 150 miles of river up stream, the two bear-traps provide a total discharge area of 2 730 sq. ft., or more than double that at Dam No. 18. The result is that both the bear-traps at Dam No. 18 can pass less than one-half the quantity of water that can be passed by one of the two bear-traps in the dams above, the combined capacity of which is about sufficient for a 9-ft. stage in the open river, the maximum stage on which it is necessary to operate the dams.

All additional weir area necessary at Dam No. 18 must be provided either by lowering the wickets in the Chanoine weir, for which it was designed, but is little used, or by lowering the wickets in the navigable pass, which was not originally intended, but which is now the usual practice. The amount of weir regulation necessary in this dam is further increased on account of its location between the mouths of two large tributary streams, the Muskingum River, 8 miles above, and the Little Kanawha River, about 4 miles below. These streams are subject to quick rises, with consequent sudden increases in the volumes of water poured into the pools above and below Dam No. 18, making quick action frequently necessary to provide for the sudden change in river conditions. The small discharge area of the bear-traps, therefore, makes frequent additional discharge area necessary for pool regulation. For this, the Chanoine wicket weir was designed, but it is an unsatisfactory and inefficient device. Like the weirs of this type used in nearly all Ohio River dams until a few years ago, it has been a failure and is little used. The unsatisfactory operating results of this weir are in part due to the elevation at which the wickets are hinged. At all other dams where such weirs have been used, the hinge points of the wickets are sufficiently above the center of resultant water pressure to prevent the wickets going on swing. At Dam No. 18, however, as described by the author, the hinge points were located so as to let the wickets swing automatically when the pools rise, in order to increase the discharge opening necessary in the dam. This feature has not been a success. The wickets will frequently swing when not necessary for pool regulation, to prevent which it is necessary to chain them to the service bridge. The idea of automatic swinging of Chanoine wickets for pool regulation cannot be successfully applied on Ohio River dams. The rotation of wickets on their hinges is influenced by both the upper and lower pools, whereas, it should be dependent only on the stage in the upper pool. As there is no uniformity in the differences of elevation between the pools at varying stages, it is impossible to locate the hinge points on the wicket so that they will trip at a predetermined stage of upper pool.

Another factor making it impracticable to use this method of pool regulation is that when the wickets are on swing, the steel frames and bars, known, respectively, as the horses and props, by which the wickets are supported, hold so much drift above them that not only is the discharge capacity considerably reduced, but it is practically impossible to release the drift and right the wickets to close the opening, without lowering the whole dam to reduce the head, and, then, only with an expenditure of much time and labor. Therefore, when such wickets are operated, they must be completely lowered, but this is difficult and slow, particularly with the special winch provided. This winch, although designed for the purpose, is another feature contributing to the impractibility of operating the wicket weir. As stated by the author, too much time and labor are required. The winch is driven by a gasoline engine and is neither suitable in type nor has sufficient power. Even if a steam engine of sufficient power was used, the wickets could not be handled satisfactorily with it, on the heads necessary. The most difficult part of such an operation is the righting of the wickets after they have gone on swing, the nature of

which operation is shown by the author's Fig. 10. The difficulty of this operation cannot be appreciated by any one unfamiliar with it. Operation of the weir with the maneuver boat is a practical impossibility, because one bear-trap is between the weir and the lock side of the river, thus making it necessary to take the boat across the head of the open bear-trap, a difficult and dangerous operation.

These difficulties have resulted in the practical abandonment of the Chanoine weir as a regulating device at Dam No. 18 and other Ohio River dams. Regulation that cannot be done with the bear-trap, is now done with pass wickets, with the maneuver boat. This is possible for such heads as exist after the bear-traps have been opened and the difference in pool levels has been reduced. If the Chanoine weir was between the navigable pass and the first bear-trap, instead of between the two bear-traps, the service bridge could be abandoned and the shorter weir wickets operated with the maneuver boat. This method of pool regulation, however, is much slower and requires considerably more labor than regulating with bear-traps. The wickets also deteriorate rapidly under such hard service and make frequent repairs necessary. For these reasons, wicket weirs are not a satisfactory and efficient substitute for the successful bear-trap weirs developed and standardized on the Ohio River.

The preceding remarks concerning wickets relate entirely to the old Chanoine type. The author describes a new type, the Bebout wicket. Some of these wickets have been used within the last few years, for pool-regulating weirs, as a substitute for one of the two large bear-traps that previously were included in the standard design of Ohio River dams. As described in the paper, these wickets will trip automatically, but they must be raised with a maneuver boat the same as Chanoine wickets. The author cites twenty-four advantages in the use of these wickets. Several years' experience with them has convinced the writer that not all of the claimed advantages can be realized in practice. On account of their automatic tripping feature, these wickets may be used with much benefit and success in some works, especially for weirs in dams where there is not sufficient back-water to effect their tripping, but neither these wickets, nor those of the older Chanoine type, can be used satisfactorily as a main regulating weir in Ohio River dams. The Bebout wickets might be used with benefit for a part of the navigable pass, as will be subsequently explained.

The Bebout wickets are hinged near the middle, like the Chanoine type, but unlike the latter, they lower themselves completely when the resultant pressure is above the hinge point, leaving an unobstructed opening in the dam, thus increasing the discharge capacity and avoiding the holding of drift as in the case of Chanoine wickets, which do not lower automatically, but only go on swing. Leaving an unobstructed opening in the dam is of great advantage, but the automatic lowering feature of the Bebout wicket, just as the automatic swinging of the Chanoine wicket, although theoretically advantageous for regulating weirs in practice, is a detriment, because the automatic tripping cannot be controlled, as previously explained in connection with the swinging of the Chanoine weir wickets at Dam No. 18, and in most cases occurs at other than the theoretical tripping stages.

All the Bebout wickets so far installed, except in one case, have been substituted for bear-traps, replacing one bear-trap of the two previously installed in each dam. In one dam, both the bear-traps were replaced by the wickets. This has not resulted as favorably as anticipated by those responsible for the change and only recently has been abandoned and the two bear-traps have been re-adopted in the standard design for Ohio River dams. The wickets trip too frequently when not necessary for pool regulation or more of them trip than are required. They must be raised with the maneuver boat, the time for which cannot be chosen, but may occur any hour day or night. This requires considerable time and a crew of men that is not available from the regular lock-operating force, except during the day shift. When such maneuvers must be made during the remainder of the twenty-four hours, some of the employees on the regular day shift must be called. This is unsatisfactory and, furthermore, the maneuvers cannot always be made quickly enough to avoid objectionable irregularities in the pool stages. Also, the time consumed by the employees in such duties is usually at the expense of other important activities. In the Wheeling U. S. Engineer District, which includes the dam described by the author, there are dams with two bear-traps, dams with one bear-trap, and one dam without any bear-trap. The force of men employed is the same for the dams with one bear-trap as with two bear-traps, but the loss of morale and increasing complaints as to the amount of work at those dams which have only one trap, and the frequent calls for duty on the dam at all hours of the day and night, make it appear that, in a short time, additional force will be required. At the dam where no bear-trap is used, and all regulating is done with wickets, it is now the practice to employ four extra men during the operating season of about nine months. Therefore, instead of the substitution of the Bebout wickets for a bear-trap requiring a less number of men for operating the locks and dams, as claimed by the author, the facts, as shown by experience, are that the labor is much increased and that it is not feasible to operate such a dam with a smaller force, but that probably such operation will require a larger force in the future. Also, the saving in cost effected by substituting wickets for bear-traps, cited by the author as another of the advantages, is true only for the cost of construction. The cost of maintenance and operation is increased, the amount of which is not known, but probably is at least enough and perhaps more than necessary to compensate for the saving in first cost. The result, then, is no gain financially and a much less efficient and satisfactory method of pool regulation. It is the considerations just cited, which have convinced the writer that, in a long series of dams, the most satisfactory and the most economical appliance for regulating weirs is the bear-trap, as developed on the Ohio River. Enough of them should be used so that when more than their full capacity is required, except in rare cases, it will be time to throw down the dam and use the open river.

The Bebout wickets could be used with benefit for a part of the navigable pass at the end adjacent to the first bear-trap and hinged so high as to trip automatically only when the upper pool has risen to such a depth over the top of the wickets, that the whole dam should be put down. These conditions would usually occur only when the river reached a stage where control of the

dam had been lost and the dam could not be lowered in the regular way by the maneuver boat. The automatic lowering of the wickets would then open a part of the dam and probably lower the upper pool sufficiently to make it possible to lower the remainder of the dam with the maneuver boat. The wickets installed in this way in a dam would afford a considerable protection against having the dam caught up on a stage of river when the lock is submerged and out of commission and navigation cannot pass over the dam. This accident has occurred a number of times, and any protection against it is worthy of consideration.

It seems proper in this discussion to refer to the problem of operating a long series of movable dams, such as that being built in the Ohio River. The problem is to raise the dams on a falling river as it approaches the minimum open-river navigable stage in such a way as to hold the water in the series of pools with a depth sufficient to maintain navigation. If the dams are raised too soon, no particular harm is done except that in case of an immediate increase in the natural flow instead of the expected decrease it may be necessary to lower the dam again and thus the labor of an unnecessary operation will have been incurred. If, however, the raising is delayed too long, the quantity of water in the river channel may be insufficient to fill the pools, and it may take several days for the natural flow of the river to supply the shortage. If one or more of the upper dams of the series have this trouble, they put on needles to close the interstices between wickets and, sometimes, even caulk the spaces with weeds, ashes, etc., so as to hasten the filling of their pools. This immediately results in still further decrease of flow into the pools above the dams in the lower section of the series, aggravating their trouble. Until construction of the Lower Ohio River system of dams is completed, there are and will be stretches of open river through which considerable navigation is attempted. Owing to the great cost of dams and the expected troubles in construction and operation, it may be that the original intention to provide a series of dams all the way to the mouth of the Ohio River will be abandoned, and that navigation in the lower end of the river will be provided by open-channel regulation. In this case, an abrupt stoppage of the natural flow due to filling of the pools in the upper section of the river will cause sudden decreases in navigable depth in the lower part, which will be highly objectionable to navigation.

The ideal solution would be to raise all dams at or before the moment when the water contained in the channel is just sufficient to fill the pools. The operation of a movable dam at any given moment, however, is a practical impossibility. The maneuver boat must be moved to its place, each wicket must be raised separately, and accidents and delays occur. In general, it takes a whole day to raise a dam and unless the labor charge of operation is to be immediately doubled or trebled, it is impracticable to keep a crew available at all hours of the day and night. The river might be falling at the rate of about 1 ft. per day and at the close of the day's work the stage might be, say, 1 ft. above the ordinary raising stage, in which event the lockmaster would expect to raise the dam beginning the next morning. Late in the afternoon, however, several lockmasters farther up the river might have had to raise their dams because of the falling of the river to the closing stage. This produces a "cut"

in the flow, and the lockmaster further down the river finds his stage falling so fast that he cannot get out on the dam and raise it in time to catch his pool. When he gets his dam up, he has to put on the needles and then the men farther down the river have even worse trouble.

With dependable communication by telephone and telegraph between dams, these troubles can be and are very often avoided, but the existing communication is not infallible. Some of the dams are on country telephone lines having from one to a dozen parties, because no other commercial service is available, and frequently all efforts to keep in touch with operations at the other dams fail. A private line down the Ohio River would cost more than $500 000 and entail an annual expense for upkeep, which would hardly be justified by the present commerce. Recent inquiries have been made as to the possibility of using a radio telephone system of communication, and it may be that some such system will be satisfactory. Reliable liaison between the dams is an essential feature of a series such as that on the Ohio River.

W. H. McAlpine,* M. Am. Soc. C. E. (by letter).—The writer has read this paper with much interest, especially the conditions to be fulfilled in the design of the weir and the computations thereon.

The author's calculations "to determine whether the weir will regulate the upper pool when the water is at a 10-ft. stage" (Condition 1), by the formula, $Q = m\ (L'\ H')\ \sqrt{2\ g\ (h + Z)}$, could be made clearer by a statement of the relations of the zero of gauge to elevation of weir sill and pool level or crest of dam. It is not essential (Condition 1) that the weir have sufficient capacity to pass all the discharge at any special stages such as a 10-ft. stage, as part of the pass wickets can be thrown for that purpose. It is believed that the author has taken great liberty in assuming that values of m, derived from observations where the "swell head" was about 0.35 ft., are applicable to a case where the "swell head" is assumed as 1.7 ft. It seems questionable whether this formula should be used for cases of "swell head" as high as 1.7 ft. It is believed that a submerged weir formula is more applicable to the case. Using Francis' formula, with values of n deduced by Herschel, we have:

$$Q = 3.33 b\ (n\ H)^{\frac{3}{2}}$$

$$b = 500;\ n = 0.63;\ H = 11.837$$

Solving, Q = discharge = 33 900 cu. ft. per sec., instead of 57 700 cu. ft. per sec., as found by the author. The formula, $Q = m\ (L\ H)\ \sqrt{2\ g\ (h + Z)}$, appears more applicable to Condition 2, and its use is better illustrated in the paper† by the late Mr. Thomas, referred to by the author. The lack of authentic experimental data as to the proper values of m makes the use of this formula unsatisfactory. It is believed that systematic observations should be made at movable dams to secure more reliable and complete data as to the proper values of the coefficient, m, under various conditions.

* U. S. Asst. Engr., Louisville, Ky.

† *Transactions*, Am. Soc. C. E., Vol. XXXIX (1898), p. 471.

For investigating Condition 3, the author uses the formula of Chanoine and De Lagrene, namely,

$$Z = m\, v^2 \left(\frac{S^2}{S_1^2} - 1\right) \frac{1}{2\,g}$$

in which,

Z = "swell head";
v = mean velocity (before construction of works);
S = discharge area of river before construction of works;
S_1 = discharge area of river after construction of works;
g = 32.2.

Z is assumed as 0.25 ft. and m as 1.05, instead of 1.5, when the "swell head" is reduced from 0.5 to 0.25 ft. After substituting the other known quantities, the value of S_1 = discharge area after construction of works, is found to be 18 250 sq. ft. It is not understood why the value of Z is assumed and the value of S_1 calculated, as the dimensions of the weir and the pass have already been determined, at least tentatively, to satisfy Conditions 1 and 2. It would appear preferable to substitute the tentatively found area, S_1, and calculate the value of Z to determine whether it falls within reasonable limits. No authority is indicated for using $m = 1.05$ instead of 1.5, the value of the coefficient used by the late Mr. Thomas in the paper referred to previously, for cases when the lock-gates are open. The writer has never found any justification for the use of 1.5 for the value of m in the formula, when applied to a lock in a large river, for a case when the lock-gates are open or for any other condition. The writer has compared the value of the "swell head", as determined by this formula, in a number of cases on large rivers with the actual "swell head" and has found that the value of the coefficient, m, should be only slightly in excess of unity. Probably the value of 1.05 given by the author is about correct for the case in question. It is possible that in a narrow cross-section of river, the contractions due to lock walls, piers, etc., might be sufficient to justify a coefficient of 1.5, but certainly not in a wide river, with a dam composed largely of weir and pass sills.

Having found or assigned a value for Z, the author calculates the mean velocity for critical high stage, which is assumed to be at the top of the lock wall, by the formula:

$$V_1 = \sqrt{2\,g\,(Z + h)}$$

in which,

V_1 = mean velocity after construction of dam;
Z = "swell head";
h = velocity of approach prior to construction of dam.

The use of the two previous formulas appears to furnish a rather unsatisfactory and roundabout method of determining the velocity of the section. The values for "swell head" are rather meaningless to the average individual, unless converted into terms of velocity. Unless one is familiar with the subject, one has little idea whether a value of 0.5 or 1.0 is excessive. However, one knows at once whether a velocity of 5.7 or 8.0 ft. per sec. would be excessive. Also, the value found for "swell head" in the formula does not

represent the entire head due to velocity of the current at the dam. To find the total velocity head, the calculated head due to velocity of approach prior to the construction of the dam must be added to the "swell head". In other words, if it is desired to compare the actual measured head due to velocity at the dam with the results from the formula for "swell head", the calculated head due to velocity of approach prior to the construction of the dam must be added to the value found for "swell head". Although the two formulas, $Z = m\,v^2 \left(\frac{S^2}{S_1^2} - 1\right) \frac{1}{2\,g}$, and $V_1 = \sqrt{2\,g\,(Z + h)}$, may be used to determine either the mean velocity after construction of the works (V_1), with an assumed discharge area of dam (S_1), or *vice versa*, the general formula, $V_1 = \frac{Q}{S_1}$ may be used for the same purpose.

Let

V_1 = mean velocity at the dam after construction;
Q = discharge, in cubic feet per second, as determined by the rating curve;
S_1 = discharge area, in square feet, of proposed dam; and
S = discharge area before the construction of the dam.

As $V_1\,S_1 = V\,S$, $V_1 = \frac{V\,S}{S_1}$; but $Q = V\,S$; therefore, $V_1 = \frac{Q}{S_1}$.

If a coefficient other than unity must be applied to allow for sudden contractions, it may be applied to the general formula, $V_1 = \frac{Q}{S_1}$, as well as the formula used by the author. Both the formulas, $Q = m\,(L\,H)\,\sqrt{2\,g\,(h + Z)}$, and $Z = m\,V^2 \left(\frac{S^2}{S_1^2} - 1\right) \frac{1}{2\,g}$, are modifications of the general formula, $Q = A\,V$, and their value depends on the completeness and reliability of the observations made to determine proper values of the coefficients to be applied under various conditions.

Some of the areas of the cross-section of the river bed given in Table 3, for various stages, are apparently in error. For example, the difference in area between the 10-ft. and the 11-ft. stages is given as (20 540 — 18 350) 2 190 sq. ft.; and between the 11-ft. and the 12-ft. stages, there is a difference of only 1 270 sq. ft. Again, S is given as 24 600 sq. ft. for a 16.4-ft. stage, or an increment of only about 600 ft. for each additional foot, assuming the area of 21 810 sq. ft. for a 12-ft. stage to be correct.

The principal object of this discussion is to bring out the desirability of more complete observations as to actual velocities created by the construction of locks and dams and other obstructions, in order that reliable coefficients may be available for the formula selected for use.

GARDNER S. WILLIAMS,* M. AM. SOC. C. E. (by letter).—Several years ago, the writer was confronted with the problem of providing, in a storage dam, a gate

* Cons. Engr., Ann Arbor, Mich.

through which large quantities of logs could be sluiced at variations of pond level through a range of 20 ft. The width of the opening required by the lumbering interests was 30 ft. After considerable investigation, his attention was directed to the three-leaf bear-trap gate of the so-called Lang type, built in 1894, on the Chippewa River at Chippewa Falls, Wis. It had a length of 80 ft., with a rise of 6 ft., and had then been in service more than 20 years. An examination of the design of this structure, which was of timber, indicated that by the use of steel the type could be readily applied to a rise of three times that in the existing example. A similar timber structure came to notice later. It was built in 1891 on the St. Croix River at Nevers, Wis., and had a crest length of 80 ft. and a rise of 16 ft.

The so-called Island Lake Dam of the Great Northern Power Company on the Cloquet River, about 22 miles northeast of Duluth, Minn., was thereupon equipped with a bear-trap gate of the Lang type, having a rise of 20 ft. and a span of 30 ft. As far as the writer is aware, this is the highest rise under which a bear-trap gate has thus far been operated. The gate was placed in service in 1915 and has been in satisfactory use since.

The success of this gate has led to the use of this type by the writer for the discharge of flood waters in connection with power developments on the Huron River in Michigan. At the Geddes Plant of the Detroit Edison Company, there are two such gates, each having a span of 24 ft. and a rise of 11 ft. At the Superior Plant of the same Company, the writer has installed a similar gate, the operation of which is made automatic by the use of a siphon which exhausts the water from under the gate when the pond rises above a desired level. The seal is broken when the water surface is lowered, and the gate then rises to its original position.

As the operation of these gates simply requires the opening or closing of an inlet or outlet valve, they can be readily manipulated by one man, and if used in connection with a power plant, motors can be installed on the valves and the apparatus controlled from the power house at any desired distance.

A description of the Island Lake Dam has been published,* as well as a valuable Symposium on Movable Dams† which is interesting not only as to matters of design, but also as to the history of the bear-trap gate. The Sector Dams of the Sanitary District of Chicago at the Lockport Power House have also been described,‡ as well as the 160-ft. bear-trap dam§ above Lockport.

In the gates designed by the writer, it has been found desirable to use rollers under the up-stream end of the idler. Such rollers had not been generally used on the timber structures previously built, but when metal members are in contact, rollers are frequently necessary.

MORRIS KNOWLES,‖ M. AM. SOC. C. E. (by letter).—The author's noteworthy contribution on the design and construction of movable dams on the Ohio River is of timely interest to the student of rivers and of the effects

‖ Cons. Engr., Pittsburgh, Pa.

of man's regulating and restrictive works thereon. It may be worth while to note some of the discussions and opinions as to the effects of movable dams on flood heights and the care necessary to insure sufficient water for lockages during times of low flow.

On page 98, the author states:

"It is well known that a project substituting fixed dams for movable dams would be less expensive; but the requirements of navigation *and the popular fear of an increase in flood heights* made the building of fixed dams in this river appear at that time to be impracticable."*

And, on page 140, Col. Harts states:

"The Ohio is subject to extreme floods. Sometimes, as much as 70 ft. in range is recorded, and great injury and loss invariably result to the towns along the banks. Nothing could be allowed in the bed of this stream that would be likely to increase this range, *and in the public mind fixed dams were objectionable for this reason.*"

The writer remembers the discussion and conferences that took place in 1915 when the project for the substitution of a fixed dam at Emsworth, about six miles below the Point at Pittsburgh, for the movable type of dam at Davis' Island, called Dam No. 1, was under consideration. Many were apprehensive that this new dam, about 21 ft. high above the bed of the stream, would seriously increase the flood heights at Pittsburgh. The writer was asked to review the situation for the City of Pittsburgh and the Pittsburgh Flood Commission. He was much gratified to report, after many studies and calculations, that a disastrous flood of 35.5 ft., such as occurred in 1907, would be increased at the Point by less than 1 ft. by the erection of such a fixed dam, and that an extreme flood, 10 ft. higher, which might happen by a combination of fortuitous circumstances, would be increased to a negligible degree. Thus, when this report became known, much of the opposition to the fixed type of dam at this location disappeared.

Much has been said about the tightness of wickets, gates, bear-traps, etc., and the attendant possibility that, during low-water stages, there may not be sufficient water for the large number of lockages required for full navigation potentialities. The author states:

"Considering the question of tightness, Condition 7, it is believed that bear-trap dams can be made as tight as any other type of dam. Needles, curtains, gates, and, possibly, other types can be made tighter than wickets. With the use of wickets, calculations should show a shortage of water not more than once in 10 to 20 years. * * * Computations indicate that, with pass wickets 15 ft. high, with weir wickets, 12 ft. high, and with the pass and weir of the lengths proposed, the leakage through the interstices between the wickets will about equal the discharge of the river at a 3-ft. stage. Therefore, during several weeks of each year, needles over the interstices will be necessary."

Again, on page 139, Col. Brown states:

"In the operation of this system of locks and dams, much trouble has been experienced by reason of inability to raise the dams at stages higher than about 9 ft. This results in the impounding and holding back of the discharge of the river in the pools of those dams that are raised, with a consequent rapid

* The italics in this and other quotations in this discussion are the writer's.

falling off in the discharge of the river at points lower down. * * * So great has this effect on the discharge of the river become, that at times much delay and obstruction to navigation has been experienced at and below Louisville, by reason of the manipulation of the dams at and above Cincinnati. As the number of dams in operation increase, the effect on the lower part of the river will become more and more marked, and, at times *may result in an almost complete absorption of the discharge of the river* if great care is not exercised in the raising of the upper dams."

That this fear of insufficient lockage on streams made artificially navigable by locks and dams is a real menace, is shown by the following statement from the report of the Pittsburgh Flood Commission, published in 1912, after a long period of careful investigation and research:

"Under present conditions there are serious troubles with shortage of water on the Monongahela River during dry weather. * * * At such times the pools farthest upstream are drawn down to furnish water for the pools nearer Pittsburgh, and through navigation is impossible, the upper pools being sometimes lined with barges waiting for water to float them downstream. * * * The reports of the Chief of Engineers of the United States Army give the minimum discharge of the Monongahela as 160 sec-ft. which occurred in 1895, the dryest season in recent years. This is only about two-thirds of the discharge of 244 sec-ft. necessary to supply water for 180 lockages, even if there were no other losses."

It thus appears there is danger when complete navigation facilities will have been provided and if they are utilized to the utmost of traffic capacity. The report quoted previously states elsewhere that the low water of the Monongahela will be increased to six times and that of the Allegheny to three times its minimum by the use of storage reservoirs. The Ohio at Wheeling, W. Va., 90 miles below the point of particular observation at the time of the study, will be raised 2.3 ft. at the time of lowest stages.

Surely an amplification of such a system is all that is needed further to improve conditions farther down stream. It is a mistake to argue that the beneficial effect of storage is negligible, except just immediately below a reservoir constructed for such a purpose. The effects on flood flows and the raising of low stages are likewise noticeable many miles away. The writer holds no brief for contemplated accomplishment of navigable depths by letting out stored waters as a general and universal proposition, but to say that such have no use in augmentation and helpfulness is an unnecessary attempt at a reversal of the laws of hydraulics.

On page 133, Mr. Thomas P. Roberts has stated,

"It has been proved that to reduce materially the height of great floods at Pittsburgh, restraining reservoirs should be as near as possible to the city, for the flood-producing storms reaching Western Pennsylvania are only rarely more than 90 miles in width of excessive precipitation. * * * Had the 1913 storm moved eastward only 80 miles farther, careful study indicates that, at Pittsburgh, the flood would have been at least 15 ft. higher than the record flood of 1907. It is useless to attempt to estimate the damages which would have resulted from such a flood to the towns, bridges, etc., above Pittsburgh. * * * *To talk of restraining reservoirs for such floods, at least for the area above Pittsburgh,* is waste of time."

The carefully prepared studies in the report of the Pittsburgh Flood Commission, previously referred to, which was approved by a Board of United States

Army Engineers as to practicability and feasibility, in 1913, states the highest known flood at Pittsburgh, that of 1907, would have been reduced 10 ft., or to a stage of 25.3, only 3.0 ft. above danger, by the construction and proper manipulation of seventeen selected reservoirs out of a total of forty-three possible sites. Other floods, which had occurred over a period of 50 years, would have been reduced below the danger line. Surely this controverts such an extravagant statement of the over-zealous objector. It is a good principle of life to secure the good we can, even if one's 100% desire cannot be obtained.

In this connection, it is interesting to note the remarks by Col. Brown on page 139:

"To meet this difficulty, a comprehensive scheme of control of operating the dams will have to be devised, so that constant reports as to the stages of the river and variations of discharge may be received at a central point, at which will then be determined the proper time for the raising and lowering of all dams, thus regulating them so as to affect the discharge in the lower parts as little as possible. A telephone system is being provided, connecting all dams to a central point, which will probably be Cincinnati, and that will be the point from which this centralized control will be exercised. After some means can be devised whereby the dams can be raised at stages above 9 ft., much benefit will be gained, and it is understood that attempts are now being made to devise some method of raising the dams at higher stages."

This is just the sort of managerial control that is exercised in inter-related gravity water supply systems and is exactly what the Pittsburgh Flood Commission planned for the comprehensive system of reservoirs proposed by it.

The author's remarks regarding the Government's activity in water transportation evidently caught the attention of Maj. Adams, who pertinently asks the question in conclusion:

"What would the situation be if the waterways had been improved at the expense of private capital, which always demands interest and return of the original investment? This problem looms large to the rail carriers and their security holders."

Again, as Col. Harts so aptly states on page 142:

"The supreme test of the public value of any inland waterway must always be an economic one. * * * How many of the inland streams, on which extensive navigation projects have been built, can now meet this test?"

It is hoped to have soon a legislative determination, based on an enlightened public opinion, that munificent expenditures for improvements to navigation are only warranted—if judged alone, without other effects as to the economic advantages to transportation to be obtained thereby—when all the fixed charges and overheads, as well as operating and maintenance expenses, to be borne either directly or indirectly by the traffic, are less than for some other means of transportation and distribution of products. When this enlightened day comes, perhaps there will be less opposition to the acknowledgment of the thesis that a stream should be considered as a whole from its source to its mouth. Thereby, many potential uses will be studied and amplified and some of the costs of the work will be distributed over many objects, and the burden to any one will be proportionately lessened.

WILLIAM M. HALL,* M. AM. SOC. C. E. (by letter).—Mr. T. P. Roberts seems to think that an erroneous inference may be drawn from the paper, to the effect that his distinguished father not only recommended movable dams, but recommended the particular types of movable dams finally adopted. Such interpretation was not intended. To be more exact, on page 57 of the report of 1870 by the late Mr. W. Milnor Roberts, reference is made to a "plan of movable hydraulic gates for chutes designed by T. R. Brunot", and there are other references to movable dams in that report. On page 132, a definite recommendation as to the character of the improvement proposed states that:

"from Pittsburgh down * * *, slack water navigation would appear to be the most desirable, but for the reasons which are given in my study of the plan of locks and dams, I think that none but low dams with chutes should ever be placed there."

The writer believes it to be evident that Mr. W. Milnor Roberts fully intended that the chutes should be closed with some type of movable dam. As narrated by Mr. T. P. Roberts, for 30 years or more prior to that report and recommendation, much interest had been manifested in the type of project for the improvement to be adopted, and several pamphlets were printed and distributed describing the proposed improvements and their respective advantages. The definite recommendation by Mr. W. Milnor Roberts is the earliest known to the writer for the design of dams with a movable part for the purpose of reducing the height of the fixed part. At about that time, Addison M. Scott, M. Am. Soc. C. E., under direction of the late Gen. W. P. Craighill, U. S. A., Past-President, Am. Soc. C. E., was commencing the improvement of the Great Kanawha River. He visited Europe, inspected the movable dams of France and Belgium, recommended the use of the Chanoine wicket for the dams of the Great Kanawha improvement, which were adopted by Gen. Craighill and the War Department, and commenced their construction in the early Seventies. A few years later, Col. Merrill adopted the Chanoine wicket for the movable part of Dam No. 1, Ohio River. It is believed that the first Chanoine wickets built and placed by the United States Government were on these works. With that beginning, as stated by Col. Harts, Division Engineer, Central Division (including the entire river), much work and study have been required to plan the project, with all its mass of details as it is now formulated. The writer has read many of the engineering reports on the river, made during the past 70 years, and fully concurs with Col. Harts in regard to the character of the improvement, and that the best, of the many types of construction proposed, have been selected.

The remarks on page 96, in reference to the possible slow permanent growth in traffic, refer especially to package traffic by the public carrier, the "packet-boat" or "packet-line". On the upper river, where the channel and other conditions are favorable, barge-line traffic by privately owned barges and boats is already progressing under favorable commercial conditions, except for the interchange of traffic from barge line to railroad, which is usually believed to

* Parkersburg, W. Va.

be with a discrimination against the barge lines. Therefore, the barge traffic by privately owned barges and boats should expand as the improvement progresses down stream, and it appears to be doing so. The statement by Mr. Roberts of the tonnage capacity of some of the locks is a valuable record. However, as it is believed to include only coal in barges loaded to capacity, it would hardly be wise to use it as basic data for estimating the capacity of the Ohio River locks for passing a mixed tonnage with possibly less that 50% of coal. The important thought which the writer wishes to convey, to those not familiar with the Ohio River improvement, is that it is converting a river with a past navigation of intermittent character and frequent annual or monthly suspensions to one which is continuous, reliable, and of sufficient capacity to admit of any probable growth or expansion which may be desired in case of war, railroad strikes, or the suspension of railroad growth, or in case of other local or National calamity. With this improvement completed and properly maintained, it will be only a question of providing the requisite boats and barges and manning them and possibly of building a second lock in 25 to 50 years. It is believed that it is the part of wisdom for communities, States, and the Government to provide reserve resources in transportation, especially when it can be done at such a small first cost, and by a method which involves a minimum of cost for operation and maintenance. A highway of equal extent, permitting an equally quick expansion in tonnage by automobile, or any kind of railway, held in continual readiness for use, will cost in annual upkeep probably ten times that of the Ohio River locks, dams, and channel. Although the United States has a wonderful railway system, one of the lessons of the World War was that the transportation system was insufficient for such an emergency, hence the great importance of providing the reserve in transportation afforded by the Ohio River.

The description of the industrial conditions in the Ohio Valley, together with the economies of the project by Col. Harts, is a valuable addition to the reference thereto on pages 95 and 96. The opinions relating to river traffic are somewhat divergent, and conclusive reasons for a failure to have a great increase already in the package traffic are so difficult to determine definitely, that it would hardly be advisable for the writer to dwell on them here, but he thinks the main cause for the failure, however, is stated in the paragraphs, near the middle of page 96. The interesting discussion of the subject by Maj. Elliott, with a statement of the traffic to June 30, 1921, and the economics of the project, is elucidating, and may satisfy the suggestion by Col. Harts on page 141. As the annual traffic through some of the locks in the Pittsburgh District has exceeded 25 000 000 tons, it appears reasonable to expect that, by the time the project is completed to Dam No. 48, below Evansville and Henderson, the average annual commerce for the Ohio River will be not less than 12 000 000 tons, with an average movement of at least 200 miles, or 2 400 000 000 ton-miles. Notwithstanding Maj. Elliott's interesting discussion, it appears that, after the effects of the swollen after-war rates of interest and prices are past, the annual interest on first cost, plus the cost of operation, care, and maintenance may be expected to be about $6 000 000. These estimates make the annual fixed charges per ton-mile for the entire commerce about 2½

mills. An examination of "Poor's Manual" does not disclose corresponding figures of average cost per ton-mile for railway track maintenance plus the interest on first cost of the completed permanent way; however, the average revenue per ton-mile for all the railways of the United States is given as 7.4 mills for 1920, 6.46 mills for 1919, 5.99 mills for 1918, 4.56 mills for 1917, and 4.06 mills for 1916; that is, an average of 4.06 mills per ton-mile in 1916, the year of low prices before the war, as compared with the average of 6.62 mills for the years, 1918 to 1920, of swollen prices due to the war. Although the writer has not obtained the corresponding statistics for 1921 and 1922, it is known that the railway revenues have continued to rise, and when these statistics are completed, the average revenue for these two years will probably be nearly 1 cent per ton-mile. As it is believed that the average interest and dividend rate on railroad bonds and stocks does not exceed 5% annually and is probably nearer 4¼ to 4½%, it becomes evident that the railway rate for interest on first cost, which is believed to be about 2 mills, added to the maintenance, must be 2½ mills and probably considerably more, that is, as much as for the tonnage of the average railway of the United States as for the Ohio River, or more. As many of the railways in the Ohio Valley, under present traffic are working to their capacity, and as the 2 400 000 000 ton-miles for the river can easily be multiplied five to ten times, when such quantities of tonnage are offered, it appears that, as a transportation line for the entire valley, the improvement is unquestionably advisable, and much more desirable than additional railway trackage of an equal cost. It is believed that a good double-track railroad for the entire length of the river, ready for operation, would cost 50% more than the completed improved river.

To the public, another advantageous feature of the improvement is that referred to on page 96, "railroad low rates at competitive points", and more strongly emphasized by Maj. Elliott at the bottom of page 1284. It is so well known that water competition lowers railroad rates at all competitive points that it does not seem to be necessary to present more statistics or discussion. It appears that these advantages of emergency insurance in case of National or industrial war, and low freight rates effected by water transportation are not given due weight by many writers and speakers on this subject. The writer is so confident that this river will ultimately comply with the financial test enunciated by Col. Harts, Maj. Adams, and Mr. Knowles, that, in this particular case, these other great reserve advantages need not necessarily be used as governing factors. However, it is not clear to the writer that the test, as enunciated, is the one to be taken as the final mandate by the Government in all cases, because it is well known that the principal benefits of the railways of this country are not to the stockholders and bond holders but to the people who use them, who own property near them, and to the National body politic. The Government is now spending many times as much for highways and National paved roads as for rivers and harbors. No such test as that referred to seems to have been suggested as a condition for that expenditure. Why, then, should such a test apply and be the final criterion for river improvement any more than for public highways for automobiles,

horses, and pedestrians from which no revenue is received or expected except in the way of National prosperity and the tax thereon?

In the movement of package freight, the writer believes that a change in the present system of operation must come before the volume approaches that which should exist and be expected for a proper service to the public. It must be understood that the building up of extensive service of that character for the public requires financial responsibility, an organized and permanent force of trained agents equal to that of the railways, with no possibility of "cut-throat" competition, a continuity and permanency of service equal to that of the best railroads, some uniformity in quality of service and schedules of boats, and an interchange of traffic with the railroads, with one bill of lading only from shipper to consignee, whether or not the delivery is made by railway or by boat. With these defects remedied and such conditions made equal to those of the best railroads, there is a large tonnage of package freight moving by railways along the banks of the river which can be delivered by boats more economically and in less time than by rail, thereby resulting in economy and convenience to the public. Maj. Adams' remarks on this subject indicate that he may have overlooked the writer's suggestion that any award of special privileges should be under proper Government competitive methods and control. The essential accomplishment desired is that the "packet lines" from the head to the mouth of the river establish and maintain a permanent service, for the country people, towns, and cities, equal in accommodation, and reliability, and superior in speed of movement to the best railway service. Until such a service is realized a lack of genius as a people to manage efficiently affairs of that character will continue to be displayed.

The writer appreciates Col. Brown's discussion of the conditions in the lower river as a valuable extension of the brief reference thereto on page 98, especially as to the reasons being considered and the interesting features introduced by the omission of two or more of the dams below Dam No. 49. As he states, the short season of low water, the great fluctuations in stages, the great quantities of shifting sand, and the failure to find rock at any of the sites on which to found masonry makes the estimate of first cost high; and the shifting sand will no doubt make the cost of operation greater than that for those dams above Cincinnati. With the new 9-ft. channels through obstructing bars planned so as to have the direction of flow of the current parallel to the axis of the channel at all stages, the probabilities of success appear to be favorable.

In reading Col. Brown's statement (page 139), of the time required to place rolling gates in service after the winter floods, it should be remembered that, although two weeks' time is required at two or more locks below Cincinnati, the cases are exceptional. The delay in first maneuvers of the gates after floods is usually due to the accumulation of deposits of great depth on the gate tracks and about the gates. In the recesses which are placed so as to have a current flow over them at a rate equal to the average channel flow, the accumulation of deposit during one winter is not serious. The deposit in the recesses of Lock 18, after the three winters, 1910 to 1913, averaged 3 ft. in depth at the portals and 5 ft. at the rear ends; the maximum depth not

exceeding these averages more than 1 ft. This small depth of deposit is due in part to the location of the lock on the concave shore. Where other conditions make it desirable to select a location on a straight stretch, or on a slightly convex shore, in order to obtain the swiftest current possible, the recesses should be as far out in the channel as other conditions will permit. A location directly below a jutting point, on a bar, immediately above a bar, or in a natural eddy is likely to cause excessive deposit. Deposit is not easily remedied by covering the opening. To be effective, the covers must form practically a perfect seal, and as they must be broken as soon as the flood is past, that method is expensive.

As Col. Brown states, in this long series of movable dams there has already occurred a serious shortage of water immediately after raising the dams, resulting in stages of possibly as much as 3 ft. below the natural stage for periods of several days.

The writer has read Mr. Knowles' report to the Pittsburgh Flood Commission, referred to in his discussion. As apparently anticipated in his discussion and stated by Col. Brown, it appears that "a comprehensive scheme of control of operating the dams will have to be devised", or, at least, that appears to be desirable. In devising a complete system of control, it may be well to consider the possibility of using stored water and of obtaining some of the supply from the pools of tributaries with fixed dams now in existence, and also the further possibility of increasing such storage from dams proposed for future construction on tributaries.

The system of steel sheet-pile coffers in use for the lock and abutment at Dam No. 34, to which Col. Brown refers, was started under his direction, for the purpose of reducing the great cost of coffers for work of this class, which, on the middle section of river, is nearly $200 000 for a single lock and dam. It consists of a series of small coffers ranging in size up to 49 by 150 ft., built of a single wall of steel interlocking sheet-piling about 40 ft. long, driven in rectangular or curved forms, and braced by several tiers of 12 by 12-in. timber. This method has been tried to a more limited extent at three up-river dams, and on many smaller industrial works. This is its first adaptation to all the parts of an Ohio River lock with a deep foundation of piles. The principal advantages of the steel coffer appear to be:

(*a*) It is not so likely to be injured by floods, and permits starting coffer construction a month or more earlier than with either of the wood types.
(*b*) Less excavation is required.
(*c*) Less damage to the coffer by floods and by deposit, and less machinery in the coffer to be submerged.
(*d*) Less obstruction in the river, thereby not so much increase in the velocity of the current, or obstruction and interference with navigation.
(*e*) The coffer wall is closer to the permanent work, thereby enabling derrick boats to stand outside the coffers and place loads in the permanent work.

The principal disadvantages are believed to be in the slower progress in seasons of long low water, excess in cost during seasons when there is no damage to wood coffers by floods, and excess in difficulty of removal, especially where piles are driven deep. It is also evident that the cost of the steel coffer construction increases much faster by increase in the span between the steel walls than the distance. This cost becomes excessive when the timber braces are longer than 20 or 24 ft., and require splicing or are purchased in unusually long lengths. A comparison of the cost reports of the building and removal of Lock 34 coffer and of those of Lock 38 box coffer, which was constructed and in use during the same time, indicates that the cost of Dam No. 34 is the greater.

Maj. Adams' data of the hydraulics of the river at Dam No. 48 (Mile 804) and his description of some of the main features of the dam is a valuable addition to the paper. However, when the dam was designed, about 10 years ago, it was hardly realized what a great improvement the improved bear-trap would make in the ease of regulating the upper pools, and the great reduction it effects in the labor of operation. In recommending that one of the Dam No. 18 bear-traps be placed next to the abutment, it was expected that part of the difficulty of passing from pass to wicket weir would thereby be overcome. As indicated on pages 111 and 128, it has long since been clear to the writer that it would have been wise to have placed both traps together and adjacent to the abutment, even at the further expense of increase in the cost of bank protection. It is now gratifying to learn, from the discussions by Mr. Grimm and the late Mr. Thomas, that they also had reached the same conclusion in regard to the relative position of pass, wicket weir, and bear-traps for other dams now being designed or constructed. As the 91-ft. bear-traps can be relied on to maneuver in 1 or 2 min., up or down, without any other effort than that required in opening two valves and closing two others, and, as the up keep is small, it appears to the writer to be inadvisable to build a dam without one trap; two are preferable; and, as stated on page 129 and by Mr. Grimm on page 149, the excessive cost of the bear-traps is one of the principal reasons for not adding a third trap instead of 100 or 200 lin. ft. of weir wickets, as in the dams of recent design. However, another reason, which also must be considered, is the fact that a head of water is required to remove deposit from the trap recesses and inlet and outlet culverts immediately after the wickets are raised. The wider the bear-trap opening the longer the time needed to obtain the required head. At that particular time, in maneuvering the dam, every minute of delay is of importance to navigation. The reader should bear this condition in mind while reading the long argument (pages 159 to 164) for more bear-traps and the entire elimination of weir wickets.

Mr. Williams gives an interesting record of the trap of highest lift of which the writer knows.

In reading Mr. Duis' reference to the Dam No. 18 bear-traps and weir, it should be remembered that the dams on the upper river were not built in order. When Dam 18 was started and when the bear-traps were designed and constructed, there was not a steel bear-trap in operation on the river, or in the world, approaching it in stiffness or weight per square foot of lower leaf. At

that time only Dam No. 1, with only one 50-ft. wooden trap, had been placed in operation. The writer visited that dam in 1902, and the trap was out of service for repairs. It is the great improvement, in the No. 18 and the other steel traps with leaves of the same design, which has reduced the usage of the Chanoine wicket weir, notwithstanding the excellence of weirs of that type operated from a bridge, as long demonstrated by the eight dams on the Great Kanawha River. The six dams referred to on page 160 are Dams Nos. 1 to 6, inclusive, on the Ohio River, all of which were commenced several years in advance of Dam No. 18. Wooden traps were first designed for several of them and for some of the other dams. The change to steel for Dams Nos. 2 to 5, inclusive, was decided at about the time the No. 18 plans were completed or after. The span of the steel traps for those dams was made 91 ft. to fit masonry which had been built before the decision as to building the steel traps, and thus that span has become the standard for the river. When Dam No. 18 was designed, the regulation of all the upper pools then in operation in the United States was being done principally or entirely by the use of wickets. That method had been used extensively in Europe for many years. The operation of wickets from a bridge is the only method of pool regulation on the Great Kanawha. Although the improved bear-trap is superior to the wicket as a regulating weir, under the direction of the builder of the Kanawha dams, their operation appeared to be excellent until the No. 18 type of trap was placed in commission. During the 5 years of operation of Dam No. 18, under the charge of the writer, the wicket weir was used as an important factor in regulation and operation. In later years, due to the ease of maneuvering the bear-traps, the inclination appears to be to use the traps for that purpose to their limit before seeking assistance by use of the wickets. Although the improved bear-trap has reduced the use of the weir wickets, it seems somewhat premature to state that wickets are "obsolete". This seems especially true as long as those in authority continue to design and build new dams with wicket weirs, as indicated in the discussions by Mr. Thomas and Mr. Grimm. The writer regrets that they did not amplify more of the subjects introduced so briefly in the paper.

Besides the improved arrangement of wicket weirs in Dams 34, 36, and 38, described on pages 149 and 151 it is gratifying also to note that, in some of the new plans, the filling and emptying of culverts for the bear-traps is being planned about as suggested in Paragraph (*c*), page 130.

In referring to the formula, $Q = m\ (L'\ H')\ \sqrt{2\,g\,(h + Z)}$, page 103, Mr. McAlpine pertinently says that "the lack of authentic experimental data as to the proper values of m makes the use of this formula unsatisfactory". The writer diligently sought a more applicable formula, and more data as to values of m, without satisfactory results. He doubts if any exist. It is believed that satisfactory data must be obtained from completed dams in operation, and not from models. In the particular case used on page 103, from observations of the discharge through the completed dam, the writer believes that the actual discharge is quite close to that computed (57 700 cu. ft. per sec.), and he is confident that the discharge computed on page 165 (33 900 cu. ft. per

sec.), equivalent to the natural discharge of the river at a 7-ft. stage, is too small. The writer fully agrees with Mr. McAlpine that it is time that some of these formulas and data were tested by experiment, and that all desired values be obtained by careful observation and velocity measurements at all stages below the crest of dams.

The apparent error in the areas of discharge, referred to by him, is due to the fact that the gauge observations were made at a point about ½ mile below the dam, up to a stage of 10.7 ft., the highest stage at which observations were made. These areas, from a section at that place, were used up to the 11-ft. stage, whereas, above 11 ft., the areas were taken from the cross-section of the river on the axis of the dam.

In 1855, Mr. Herman Haupt, a Civil Engineer, published an article on the Ohio River problems, improvement of navigation and flood control by use of restraining dams, in which he says, "the control of floods, therefore, may be left to future legislation. It will be sufficient at present to attend to the improvement of the nagivation. To accomplish this object will be glory enough for one generation."

Most members of this Society were born after these words were written, and have seen engineering inventions and works, greater, more numerous, and more wonderful than those by all the preceding generations combined. They indicate a surprising vision for one of that day when the wonderful discoveries and improvements of this generation were hardly commencing.

It is a great pleasure to the writer to know that he has taken even a small part in the solution of the problems relating to the Ohio River project and improvement, one of the many great works conceived, designed, and executed by his fellow workers of this Society.

As a last word, the writer wishes to express sincere and grateful appreciation to each of the contributors for the valuable matter added to this paper, by their discussions.

Paper No. 1511

THE COMPARISON OF CONCRETE GROINED ARCHES AS AN AID IN THEIR DESIGN

By Philip O. Macqueen,* Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. Thomas H. Wiggin and Philip O. Macqueen.

Synopsis

Most engineers recognize the value of comparison as an aid in the design of practically all structures, both as a valuable check and also as a preventative of unusual errors. Comparison, however, must be used with good judgment and extreme caution, as otherwise dangerous mistakes may easily be made. Comparisons cannot be used, in some instances, with special or original structures, but these cases are a small proportion of the total.

With statically indeterminate structures, such as concrete groined arches, the use of comparison as an aid to design becomes doubly valuable. Actual design in this case is impossible, and the engineer must use empirical methods and comparisons. Empirical formulas alone could not be used safely in the design of concrete groined arches, and comparisons, therefore, become fundamentally important.

This paper presents a study of the proportions of typical concrete groined arches which have been used successfully for reservoir roofs. It is believed that the various ratios and dimensions discussed will be helpful in problems of design and that the use of these ratios will save not only a great deal of the work of preliminary design, but will serve also as a guide to more economical structures. Special types of concrete groined arches built to support unusually heavy loads, such as filter tanks, are not included in the scope of this paper.

As one of the problems of Civil Engineering the groined arch, now generally used for reservoir roofs, is an interesting anomaly. The method of designing

* Cons. Municipal and San. Engr., Washington, D. C.

the structure is empirical and from a strictly mathematical or even logical viewpoint, its exact design is impossible. This type of structure has been used, however, for more than 2 000 years, and, when carefully constructed, its safety is beyond question. It is as safe or, perhaps, safer than the ordinary arch used in bridge or in building construction. The singularity of the groined arch roof lies in the condition that a structure so simple, strong, and harmonious, is so complicated as regards a mathematical analysis of its stresses, even under a symmetrical loading. The purpose of this paper is to make a comparison of existing groined arches and to suggest several rules that should be of use in the design of such structures.

The usual methods attempted in the design of concrete groined arches are based on the principles that are used in the design of simple cylindrical arches. These methods, as applied to concrete groined arches, have been fully developed by Thomas H. Wiggin,* M. Am. Soc. C. E., and also by Leonard Metcalf,† M. Am. Soc. C. E. It is unnecessary, therefore, to repeat the complete mathematical analysis. The method, although simple, is somewhat cumbersome, and is not completely presented in textbooks. The article by Mr. Wiggin contains several methods of designing groined arches, but for the purpose of this paper, it will be sufficient to summarize briefly the generally preferred method.

In general, there are two steps in this preferred method of design: First, the selection of a groined arch of certain dimensions; and, second, the investigation of this arch for stability under the required loadings by the "hypothesis of least crown thrust." This hypothesis assumes that the true "line of resistance" is that for which the thrust at the crown of the arch is the least possible consistent with equilibrium. The strength and stability of the arch depend on the position of the "line of resistance" and the position of this line, in turn, depends on the amount, direction, and point of application of the crown thrust. The crown thrust is assumed to act horizontally at the upper third point of the thickness of the arch at the crown. The external loading in this case is considered as acting on a triangular area obtained by assuming that the arch is cut vertically along the groined lines, as this method of loading will be found to give greater unit stresses at the "joint of rupture" than other methods. As a condition of equilibrium, it is further assumed that the center of pressure will always remain within the middle-third of every joint. With these assumptions and correct data in regard to the dead and the live loads, the crown thrust and the thrust at the joint of rupture are easily (although somewhat laboriously) computed by the usual methods as given in textbooks on simple cylindrical voussoir arches. The final step in the design consists in laying out a cross-section of the arch on a large scale, and making a careful graphical check of the problem and the position of the "lines of resistance" for the various loadings.

The preferred method of design previously outlined, although cumbersome, has always produced safe structures and, therefore, it is used. With good

concrete, the factor of safety is high, as has been proved many times. Arches designed for the normal loading of 2 ft. of earth plus a live load of 100 lb. per sq. ft. have safely carried a load of 10 ft. of earth. Cases are also on record of other arches carrying heavy concentrated loads far in excess of those anticipated. As an example of a still more severe test, arches unsupported at the crown have been loaded to at least four times the allowable load, thus proving the strength of the structure. Groined arch roofs have failed, but, in each case, the failure has been due to faulty foundations, poor concrete, or to unusual stresses at certain times during construction. No cases are on record of groined arches that have failed on account of poor design or even excess loading.

* Under construction or proposed.

Notwithstanding this proved strength, however, the method of designing groined arches is empirical, and a strictly mathematical or even logical method of their design is impossible. This statically indeterminate condition is due principally to the multiplicity of the points of support so that, although the loading on the groined arch roofs is symmetrical and easy to compute, it is, nevertheless, practically impossible to develop a formula that will give a logical distribution of the stresses caused by the loading. The flat slab type of concrete structure is statically indeterminate for the same reason. The

preferred method of design for groined arch roofs is that which gives the greatest unit stresses and, therefore, the highest factor of safety. The labor involved in this method can be appreciated by the fact that the average engineer, unless experienced in this work, usually will require a month to lay out, investigate, check, compare, and finally select a groined arch for an important structure. Simple, rational formulas have replaced the lengthy methods originally used in the design of flat slab roofs so that it is consistent with economical engineering practice that, if possible, the complicated method of design of groined arches should be replaced with much simpler methods.

Strength and economy are the two most important items in the design of groined arches. Table 1 presents a comparison of thirty typical groined arches, the dimensions and general data for most of which have been taken from a table compiled by John H. Gregory, M. Am. Soc. C. E., and published in an article* by J. W. Armstrong, M. Am. Soc. C. E. The arches are listed according to the length of span. The ratios given in Columns 9 and 10 and the average thicknesses of the groined arch roofs given in Column 11, have been calculated by the writer.

Table 2 gives a summary of the various unit stresses and crown thrusts obtained in a few typical arches. In each case, the stresses were calculated by the method of "least crown thrust," as outlined previously.

TABLE 2.—Unit Stresses and Crown Thrusts Calculated by Method of "Least Crown Thrust" for Three Typical Groined Arches.

Tables 1 and 2 present a number of interesting comparisons which will be discussed in the order of their importance.

(*a*).—*Form of Groined Arch Roofs.*—The type of groined arch reservoir roof invariably selected by designing engineers consists of one in which the intrados is formed by semi-elliptical cylindrical surfaces and the extrados by parabolic cylindrical surfaces. The arches listed in Tables 1 and 2 are of this type. The elliptical shape of the intrados lends itself to a systematic arrangement at the column supports and the flattened form of the arch allows for long spans with a minimum loss of head-room. The parabolic extrados,

* *Engineering Record*, November 15th, 1913.

in its turn, gives a uniformly increasing thickness to the arch. Taken together, the two curves are excellently adapted for groined arch reservoir roofs, and it is difficult to conceive that more effective curves could be used.

(*b*).—*Length of Span.*—The length of span is more a question of economy than of strength, although strength is an important item for investigation. If the columns are long, the span should also be long, in order to save concrete by a reduction in the number of columns. The calculations must also include the average thicknesses of the roofs, and several comparisons should be made. Confidence in the strength of groined arch roofs has increased rapidly in the past twenty years, and the tendency is to use longer spans than was customary in the early days. Spans as short as 10 ft. would hardly be considered at the present time, unless the groined arch roof was intended to support very heavy loads, such as filter tanks. For columns less than 20 ft. in length, the average span used at present is about 15 ft., center to center of columns; whereas for columns 20 to 30 ft. in length, the span is usually 18 to 20 ft. A span of 20 ft. is probably the maximum which could be recommended for groined arch roofs.

(*c*).—*Crown Thickness.*—As shown in Table 1, the crown thickness in every case has been taken as 6 in., and the comparison, therefore, is simple. It might be argued that the crown thickness for the arches with the shorter spans could be less than that given, but this is not the case. With the loads in question (normally 2 ft. of earth plus a live load of 100 lb. per sq. ft.), the 6-in. thickness is about the minimum that could be recommended. Engineers feel responsible for the safety of the structures they design and hesitate to use excessively thin sections, although calculations may indicate that such sections are thicker than necessary. It will be readily seen, however, from Table 2, that a thickness greater than 6 in. is uncalled for, as all the compressive unit stresses at the crown are less than 150 lb. per sq. in. A reasonable increase in the loading, or in the length of the span, would possibly give a maximum compressive unit stress at the crown of 300 lb. per sq. in., but even this would be safe. The use of 6 in. for the crown thickness for all concrete groined arch reservoir roofs, therefore, does not seem to be unreasonable.

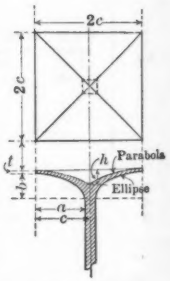

FIG. 1.

(*d*).—*Average Thickness of Roof.*—In order to make a study of the economy of the several groined arches selected for comparison, it is necessary to calculate the volume of concrete contained in each. This study is easily made by formulas derived by Mr. John H. Gregory and W. B. Fuller, M. Am. Soc. C. E. The volume, V, of a single square groined arch roof section (Fig. 1), above the springing line of the intrados, is calculated as follows:

$$V = m + n - p$$

$$m = 4b\left[c^2 + \frac{2}{3}a^2 - \frac{\pi}{2}ac\right]$$

$$n = 4c^2 t$$

$$p = \frac{2}{3}c^2 h$$

in which,

a = one-half the clear span;
b = rise of intrados;
c = one-half of the span, center to center, of columns;
h = rise of extrados; and
t = crown thickness.

When the clear span, crown thickness, and span, center to center, of columns have been selected, the quantities, $4\left[c^2 + \frac{2}{3}a^2 - \frac{\pi}{2}ac\right]$ and $4c^2t$, become constants which may be expressed by k and k'. The formula for volume then becomes:

$$V = b(k) + k' - \frac{2}{3}c^2h$$

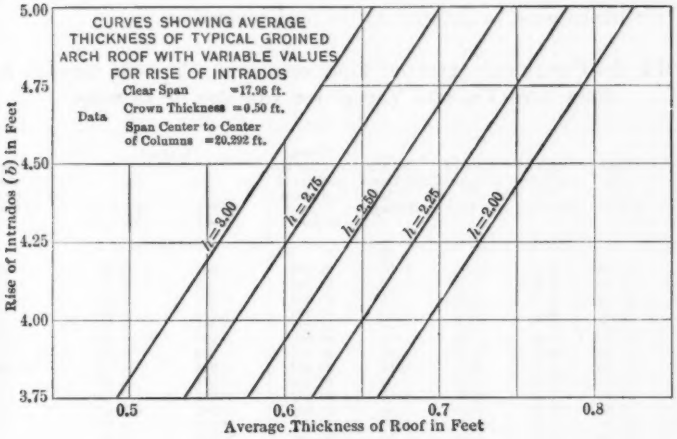

FIG. 2.

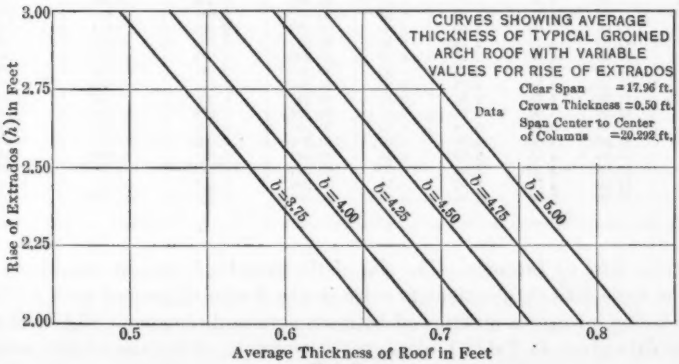

FIG. 3.

The average thickness of the groined arch roof, which is a convenient method of expressing the volume, is then obtained by dividing the volume by $4c^2$, the total projected area of the groined arch section. All dimensions should be given in feet. Tables 3 and 4 have been calculated in order to show the effect of the change of the rise of the intrados and extrados on the volume of concrete. In Table 3, the rise of the intrados has been made the variable and, in Table 4, the rise of the extrados has been made the variable. The curves, Figs. 2 and 3, have been plotted from the results given in Tables 3 and 4. It will be observed that the average thicknesses of the groined arch roofs increase directly with the increase in the rise of the intrados and inversely with the rise of the extrados. For the purpose of comparison, tables and curves similar to those just mentioned should be prepared for each new span selected for investigation. It will also be found that the average thickness decreases directly with the span. The volumes of concrete contained in the columns must be included in the final comparison.

(*e*).—*Rise of Intrados.*—The rise of the intrados is usually considered one of the more difficult questions to solve in the design of groined arch roofs, as this factor involves a question of both strength and economy. Fig. 4, plotted from data given in Table 1, shows the comparison of the rise of the intrados to the clear span. The rise of the intrados is observed to increase gradually

with the increase of the clear span, and the average rate of this increase is shown by the curve in Fig. 4, the equation of which is:

$$y = \frac{x}{3} - 1.5$$

or,

$$b = \frac{2\,a}{3} - 1.5.$$

The rise of the intrados to be used in the average groined arch roof, therefore, may be expressed as being approximately equal to one-third of the clear span minus the constant, 1.5. The effect of the rise of the intrados on the strength of the groined arch is shown in Table 2, in which it may be noted that the unit stresses and the unit shares decrease steadily with the rise of the intrados. Referring to Tables 3 and 4 and Figs. 2 and 3, however, it is observed that the average thickness of the groined arch roof increases directly with the increase of the rise of the intrados. These two conditions, therefore, are opposed to each other, and it is necessary to make a careful study of both in order to arrive at a logical selection of the most suitable dimensions.

The ratio of the rise of the intrados to the clear span is given in Column 9 of Table 1. As this ratio varies between the approximate limits of 0.20 and 0.25, the rise of the intrados, therefore, may also be expressed as approximately equal to one-fifth of the clear span for the shorter spans and one-fourth of the clear span for the longer spans.

(*f*).—*Rise of Extrados.*—The rise of the extrados used in the average groined arch is given in Table 1, in which also (Column 10) is given the ratio, $\frac{h}{b+t}$, of the rise of the extrados to the sum of the rise of the intrados and the crown thickness. In general, this ratio is observed to have an approximate value of 0.50, and the average rise of extrados to be used, therefore, may be expressed as being equal to one-half of the total rise of the arch, that is, the sum of the intrados and the crown thickness. It will be observed further that the unit stresses increase directly with the rise of the extrados and that the average thickness of the arch increases inversely with the rise of the extrados. These two conditions, therefore, are also opposed to each other, and it is necessary to make a careful study of both in order to make a logical selection of the most suitable dimensions.

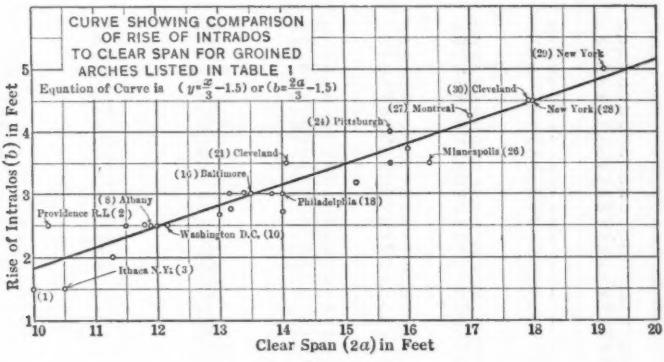

FIG. 4.

(*g*).—*Unit Stresses and Loadings.*—As shown in Table 2, the compressive unit stresses obtained in the calculations for groined arch roofs are much lower than those normally used in the design of other concrete structures. As a result of this condition, the specifications generally call for concrete containing a relatively small quantity of cement, the proportions of the mix usually selected being either 1:2.5:5 or 1:3:5. The saving in cost of the cement alone over a 1:2:4 mix, therefore, is from 5 to 10 per cent. In a structure containing 10 000 cu. yd., and with concrete at $15 per cu. yd., this saving would be about 2% of the total cost. In this connection, it is well to call attention to certain other phases of this question. In the first place, the unit stresses obtained are hardly more than guesses and it is not altogether wise to place too much confidence in the calculations. In the second place, the calculated unit shears are relatively high and there is, perhaps, danger in this condition in case extremely lean concrete mixtures are used. In general, it is believed to be unwise to use concrete mixtures leaner than 1:2.5:5, and, in many cases, a 1:2:4 concrete is perhaps preferable.

Summing up the various comparisons, it will be convenient to express the final results in the form of a few simple rules, as follows:

(*a*).—The form of groined arch roof in which the intrados consists of a semi-elliptical cylindrical surface and the extrados of a parabolic cylindrical surface is excellently adapted to this type of construction and, therefore, it should be used.

(*b*).—Spans from 15 to 20 ft., center to center, of columns may be used with safety. Economy will always call for long columns with long spans. In selecting the most suitable length of span, the calculations should always include the volume of concrete in the roof.

(*c*).—A crown thickness of 6 in. may be used satisfactorily for practically all groined arch reservoir roofs.

(*d*).—The average thickness or volume of the groined arch reservoir roof should be calculated carefully for all trial arches selected, as this factor is an important guide in the determination of the most suitable arch to be used.

(*e*).—In general, the rise of the intrados (taken only to the nearest 0.25 ft.) should be about equal to one-third of the clear span minus 1.5, that is, $b = \frac{2\,a}{3} - 1.5$.

(*f*).—In general, the rise of the extrados (taken only to the nearest 0.25 ft.) should be about equal to one-half of the sum of the rise of the intrados and the clear span, that is, $h = \frac{b + t}{2}$.

(*g*).—The unit stresses obtained in the calculations should be used with caution, and it should be realized that these stresses are somewhat problematical. In general, the proportions of concrete used in groined arch roofs should be not leaner than a 1:2.5:5 mix, and, in many cases, a 1:2:4 mix is preferable. The normal loading for the roof is usually taken as 2 ft. of earth plus a live load of 100 lb. per sq. ft.

The question of whether to use a groined arch or a flat slab roof for a reservoir is one which frequently involves differences of opinion. Both types are acceptable, although, in certain cases, one type is preferable to the other. For small, shallow reservoirs of an area of, say, less than 1 acre, the flat slab roof may be more economical, on account of the lower cost of form work, and, perhaps, better standardized methods of construction. For larger and deeper reservoirs, however, covering an area of several acres, the groined arch roof will prove much more economical than the flat slab roof.

DISCUSSION

THOMAS H. WIGGIN,* M. AM. SOC. C. E. (by letter).—The groined arch of concrete in filter and reservoir roofs was fairly well standardized in the period from about 1898 to 1910, when the large slow sand filter plants at Albany, N. Y., Philadelphia, Pa., Washington, D. C., Pittsburgh, Pa., and Springfield, Mass., as well as a number of smaller plants, were being planned and built. Probably few engineers omitted the rather farcical process of drawing lines of resistance, but a crown thickness of 6 in. appears to have resulted in all cases except where unusual conditions existed, such as an additional structure to be supported by the groined roof. Spans, rises, and depth of depressions over piers were and are subject to considerable variation, the tendency being toward longer spans, and the author's tables and diagrams will be useful in showing the dimensions in many existing plants and the relative economy of various combinations of span, rise, and depth of depression over pier, as shown by data giving the average thickness of roof.

A table giving the dimensions of twenty-seven groined roofs, prepared by Leonard Metcalf, M. Am. Soc. C. E., was published in 1903.† This table was extended by Morris Knowles, M. Am. Soc. C. E., and, again, by the writer, and is included in the writer's paper entitled "The Concrete Groined Arch".‡ On page 181, the author refers to a condensed report of this paper. This table, as extended, gives data on forty-four groined arch roofs, about twelve of which are enumerated in the author's list of thirty in his Table 1. Data on about sixty-two roofs, therefore, are available in the two tables. The writer's table also gives data on floors for fifteen of the forty-four cases.

The author's Paragraph (*b*), on page 184, explains in general terms the effect of spacing and height of piers on the design of roof. It would be useful if he could include a table or diagram showing quantitatively the effect of span. The comparative tables and diagrams relate to a single span, namely, 17.96 ft., and the statement, on page 186, that "it will also be found that the average thickness decreases directly with the span", is not apparent from the examples from practice given in Table 1. Thus, compare Lines 21 and 30 of Table 1, as follows:

Line.	Clear span ($2a$), in feet.	Rise of intrados (b), in feet.	Crown thickness (t), in feet.	Rise of extrados (h), in feet.	Span, center to center of columns ($2c$), in feet.	Ratios.		Average thickness of roof, in feet.
						$\left(\frac{b}{2a}\right)$	$\left(\frac{h}{b+t}\right)$	
21	14.08	3.50	0.50	2.00	15.75	0.249	0.500	0.618
30	17.96	4.50	0.50	2.50	20.29	0.253	0.500	0.675

In Line 21, the pier capital is 1.67 by 1.67 ft., the area of which is one-eighty-eighth of the roof area; in Line 30, the pier capital is 2.33 by 2.33 ft.,

* Cons. Engr., New York City.

† *Journal*, New England Water Works Assoc., December, 1903, p. 400.

‡ *Proceedings*, National Cement Users Assoc., 1910, p. 246.

the area of which is one-seventy-sixth of the roof area. The relatively large pier capital in the case referred to in Line 30 evidently had more effect on the quantities per square foot than the span.

To make the comparison complete, quantities in piers should be included, as the author states; it is satisfactory to do so when the height of the roof at the crown is one of the fixed quantities, as is sometimes the case, as quantities in side-walls, in that case, are not affected by rise of the arch. In some cases, head-room near the piers or the assumption that the water level shall not be above the springing line, complicates the comparisons.

Quantities in floors should also be included in economic comparisons unless the reservoir is founded on rock so that the floor does not have to support the pier load. Analyses of stresses in groined floors are even less satisfactory than those in roofs.

In the interesting pursuit of theoretical economy, it is easy to forget some practical limitations. Thus, the depression over the pier, designated by h in the author's tables and diagrams, increasing the depth of which is so important in securing economy of material, is a trouble in construction. The deeper this depression relative to the span, the more difficult it is to keep the concrete from sloughing into the depression, also, the greater the chance of unintentionally robbing the arch of thickness at the haunch and the dryer the concrete must be. Furthermore, ramming on the slope makes the concrete slough into the depression. Forms for the depression have been tried, but only experimentally as far as the writer knows. Concrete workers on groined arches become surprisingly skillful in forming these depressions, yet it would doubtless be true economy to limit the steepness of the surface slope. It would be interesting to have a line of practical limitation (similar to the deflection limit in a table of floor-beams) added to the tables and diagrams on the basis of surface slope. A contractor at his own expense would generally prefer to fill exaggerated hollows somewhat. Probably, it would be better to assume a tangent of a certain slope at the lower end of the parabola of the extrados instead of extending the parabola to the bottom of the depression. The computation for quantity would be less easy. Allen Hazen, M. Am. Soc. C. E., described the depression in the roofs of the Albany filters as a cone and not a pyramid.*

The writer's paper, to which the author refers, contains this sentence: "The groined arch, although used centuries ago, remains a purely empirical type of structure, designed, or speaking more accurately, drawn, without satisfactory mathematical analysis and used without much knowledge of the factor of safety." The author takes a similar view and concerns himself with compiling aids for empirical design. The writer treated of certain other theoretical and practical problems in groined roof construction, that are related to design and, perhaps, may be briefly mentioned.

At the edges of a filter or reservoir, the thrust of a groined arch is often opposed by the thrust of a side-wall having a section about like one-half an ordinary horseshoe-shaped aqueduct. The "active" thrust from this side-wall is much less than that of the groined arch which is comparatively flat. Mani-

* *Journal*, New England Water Works Assoc., December, 1903, p. 408.

festly, the "passive" resistance of the earth against the side-wall is called into play, or the groined roof supports itself partly by cantilever action. Shrinkage and change of temperature of the roof are sufficient to cause the construction joints along the crown to open, sometimes as much as $\frac{1}{8}$ in. One who has designed arch bridges by rigid methods, in which the distortions due to stresses and temperature are consistently accounted for, knows that a short arch, even if it is without groins, could not take up such a shrinkage without cracking. When the ties afforded by the straight elements of the arches at right angles are considered, it is evident that, during the colder weather, it is only after the formation of vertical cracks along planes approximately joining piers that the groined roof can act as a rough voussoir arch. The writer has observed many such cracks. These cracks are not dangerous, unless they happen to occur on a slope such as to release a section of roof and allow it to fall. It is only this latter occurrence, which happens very infrequently, that would deter the writer from using arches 3 or 4 in. thick in some cases. The greater the rise, the less the danger that pieces may be released. Doubtless, the load carried by arch action through the earth covering, or, perhaps, by beam action in frozen earth, relieves the concrete of considerable stress.

It was formerly thought that groined arches could carry the load without arch action, that is, by cantilever action. The idea was suggested by the safety with which wagons and horse-drawn rollers could move near the free edges of partly constructed groined arch roofs. Computation of these loads, however, showed comparatively light concentrations. Furthermore, strips of roof were constructed monolithically and a traveling load would be supported by several groins aiding each other. Foremen's stories of long unsupported edges of groined arch roofs, covered nearly to the edge with full depth of earth fill, could never be substantiated by the writer. In order to obtain an idea of the cantilever strength of concrete groined roofs where they are not supported by arch action, several isolated groin units, symmetrical about a pier, were built and tested in 1905 by the Bureau of Filtration of Pittsburgh, Pa., of which Morris Knowles, M. Am. Soc. C. E., was then Chief Engineer. The work was done under the direction of the writer, then Division Engineer. W. A. Bassett, M. Am. Soc. C. E., was Assistant Engineer in immediate charge of the construction and testing. These tests have never been published and by arrangement with Mr. Knowles are presented subsequently as a part of this discussion. Most of the data are from Mr. Bassett's final report dated February 13th, 1906.

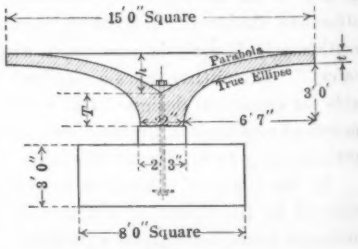

FIG. 5.

Nine groin units, each 15 ft. square, were tested. Fig. 5 and Table 5 give the dimensions, breaking loads, and deflections of these groin units. Fig. 6 gives sketches of the lines of fracture for Groins Nos. 1, 2, 4, and 6. Other data are as follows.

TABLE 5.—DIMENSIONS AND TESTS OF 15 BY 15-FT. GROIN UNITS.

Groin No.	Thickness at crown, in inches.	Thickness over pier, *t*, in inches. ‡	Age, in days.	Deflection at edge, in inches. §	Breaking Load Exclusive of Dead Weight and of Sand Used in Leveling.

†9	6	21	40	0.003	33 300	148

* Reinforced with Thacher rods.
† Aggregate composed of sand and blast-furnace slag, proportions, 1 : 2¼ : 5¾.
‡ Rise of extrados, *h*, is 21 in., or 1.75 ft. for all nine groins.
§ Deflections are not regarded as very reliable. They do indicate that deflection was small.

Foundations.—Blocks of 1:3:7 concrete, 8 ft. square and 3 ft. thick, were built in excavations made in the fill of blast-furnace slag at the "Isabella" furnaces near Pittsburgh. The fill was firm, but subject to slight jar from trains passing on adjacent freight tracks.

Dimensions of Groin Units.—The bearing on piers was 22 in. square, leaving a clear semi-span of 6 ft. 7 in., so that the full span would be 13 ft. 2 in. The rise was 3 ft. in all cases. These dimensions were the same as those used in constructing the filter plant and are given in Line 14 of the author's Table 1. The crown thickness was in general 6 in., but Groins Nos. 3 and 4 had thicknesses of 4½ in. and 3 in., respectively. The depth of depression, or rise of extrados as the author names it, was 1.75 ft., but the bottom of the depression was filled in slightly to a flat surface to make a bearing for the anchor-bolt.

Groins Nos. 6 and 8 were reinforced with a single ¾-in., Thacher reinforcing bar, which was placed near the outer edge at about mid-height in the 6-in. thickness. It was, therefore, in the form of a square, but the corners were rounded. (See plan of fracture of Groin No. 6 on Fig. 6.)

Cement Used in Groin Units.—Lehigh cement was used and the standard tests of briquettes gave the results shown in Table 6.

Aggregates Used in Concrete for Groin Units.—In general, sand and gravel dredged from the Allegheny River were used. In one case, namely, Groin No. 9, the gravel was replaced with blast-furnace slag, a greenish, vitreous, somewhat porous material, much lighter than gravel. Allegheny River sand is well graded and not too fine. The writer, unfortunately, has no records of the mechanical analyses available. The gravel is sound and hard, but rather flat, and is well graded from fine to coarse, the larger stones being about 1½ in. across.

Quality of Concrete in Groin Units.—The concrete was mixed by hand, but thoroughly. Its strength is indicated by the tests given in Table 7, of beams, 6 in. square in section, made with concrete mixed and ready to place in the groins.

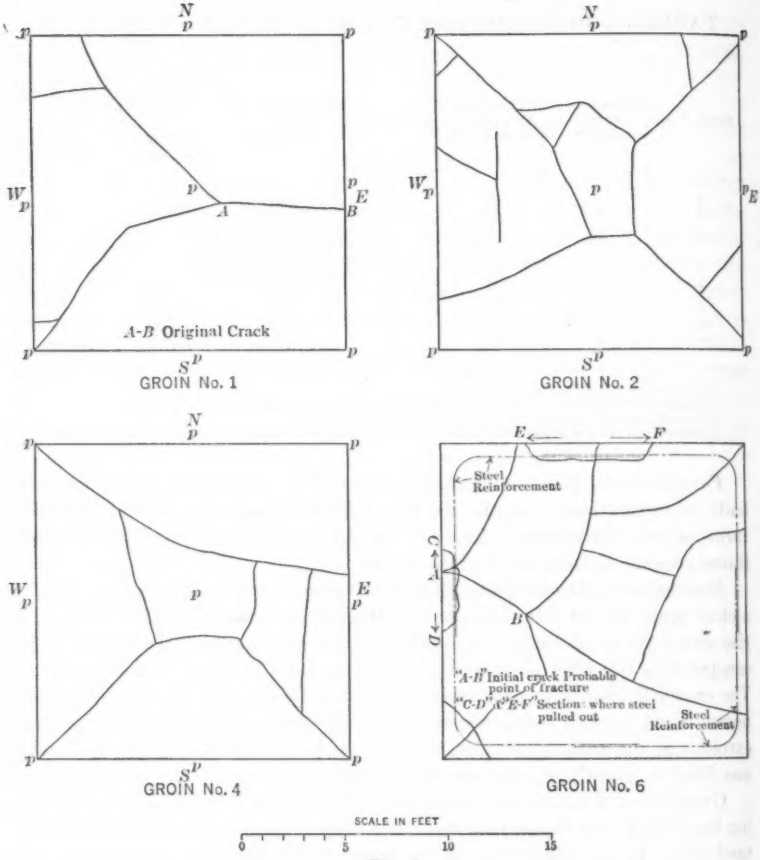

FIG. 6.

Groins Nos. 1 to 8 were made of 1:3:5 sand and gravel concrete, and Groin No. 9 was made of 1 part cement to 2½ parts sand to 5¾ parts blast-furnace slag. Much water was required for this latter mix, possibly on account of the porosity of the slag.

TABLE 7.—TESTS OF 6 BY 6-IN. BEAMS MADE FROM CONCRETE MIXED FOR GROIN UNITS.

The groin units probably did not set as rapidly as they would have in general in the filters, because there was no drain from the depression and the early summer rains kept them filled with water much of the time. The concrete, however, appeared to be fairly well set and strong.

Tests of Groin Units.—Slag was piled under the groins leaving a space of only about 3 in., in order that the impact of the fall might not break them into smaller pieces and disguise the lines of fracture produced by the loading. In spite of this precaution, it is known that many of the cracks shown on the diagrams of fracture, in Fig. 6, resulted from the fall. The fall was difficult to watch, but it is known that the initial break in nearly all cases took place near the center of a side. However, Groin No. 2 which was the strongest, apparently broke first nearer a groin line than the center of a side. Groins Nos. 1 and 5 cracked before any load was applied, owing perhaps to shrinkage stresses or jarring, or to a combination of these causes. Final failure took place at the same cracks under a light loading. Groins Nos. 3 and 4, respectively 4½ and 3 in. thick at the crown, fell down when the forms were removed, which was done at 6 days and 18 days, respectively.

Iron, in pigs weighing about 100 lb. each, was used in the loading. These pigs were piled corncob fashion on isolated wooden bases, 22 by 24 in., symmetrically placed on the level bed of sand with which the depression in the groin had been previously filled. Therefore, no tying strength was afforded by the load itself.

It appears to be a safe conclusion that groins made of good concrete and supported on piers about 15 ft. apart, will about sustain a fill of 2 ft. of earth without developing arch action. As the groins are generally concreted in strips, the strength of part of the roof would be greater, owing to the effect of continuity.

The effect of steel reinforcement was not fairly measured by tests of Groins Nos. 6 and 8, because the failure took place in the region of the lap, and the steel pulled out. In Groin No. 8, the steel was flattened, drilled, and fastened together at the splice with a number of ⅞-in. bolts. The steel broke at a bolt hole. It would probably have been better to put the laps at the corners, although the best groin—No. 2—broke at and near the corners. Computations indicate that such a small quantity of steel would not be very effective in any case. Cantilever action of groined roofs is unnatural, being inconsistent with arch action. Steel placed to aid cantilever action would be of use only to take construction stresses occurring near unsupported edges. There are better ways to provide for these stresses, as explained at length in the writer's paper referred to previously.

The author's statement on page 189 recommending concrete mixes not less rich than 1:2.5:5 is a little over-conservative, the writer believes, as most groined roofs have been built of 1:3:5 concrete, or of concrete of equivalent richness.

The author's statements as to the relative economy of the groined arch and reinforced concrete slab roofs are doubtless correct. The writer's estimates of relative cost, also contained in the paper referred to, showed that the reinforced concrete beam and slab roof costs about double that of the groined arch roof on works sufficiently large to permit repeated use of the forms.

PHILIP O. MACQUEEN,* ASSOC. M. AM. SOC. C. E. (by letter).—The results obtained by the tests, made in 1905 by the Bureau of Filtration of Pittsburgh, Pa., on isolated groin units form a valuable contribution to the subject. Tests on full-sized groins, or even models of groins, are scarce, so that the data now published for the first time in the discussion by Mr. Wiggin are particularly welcome. The results given by him in Table 5 indicate with a fair degree of clearness the general cantilever strength of a typical groined arch, and it is observed that this strength is sufficient to sustain approximately the usual full dead load of 2 ft. of earth, which the average arch is called on to bear. The failure of the arches having relatively thin sections at the crown is deserving of especial attention, as well as the general occurrence of the initial break near the center of the sides. Cantilever action, as noted by Mr. Wiggin, is unnatural in groined arch roofs, but, nevertheless, it forms an important factor of safety in many cases where joints in roofs have opened slightly due to contraction.

Mr. Wiggin has called attention to the statement made by the writer that "it will also be found that the average thickness decreases directly with the span," and has shown that this statement does not necessarily follow from the results given in Table 1. It is true that the change in average thickness of roof shown in Table 1 does not directly follow the change in span, but this is due to the personal element which has entered into the various designs. For example, it will be noted that the average roof thickness for Arches Nos. 8 and 9 are high, principally on account of the very small depressions over the columns which the designers have used in these special cases. Other sudden

* Cons. Municipal and San. Engr., Washington, D. C.

changes in average roof thickness due to somewhat similar reasons will also be observed. However, there is a general tendency for the average roof thickness to decrease with the span.

The effect of change of span on the total quantity of concrete is difficult to determine and can only be shown by making certain assumptions. Table 8, therefore, furnishes data on a set of imaginary arches in which the dimensions are made to conform in general with those recommended by the writer on page 189. It has been assumed that all the columns are square with special bases omitted and that the height of the reservoir from the floor to the under side of the roof at the arch crown is 18 ft. It has also been assumed that the floor of the reservoir is level and of the same thickness throughout.

It will be observed from Table 8, as stated by the writer on page 186, that the average roof thickness (Column 12) decreases almost directly with the span and that the total average thickness of roof plus column (Column 14) also decreases slightly with the span.

On account of its important bearing on the calculation of total quantities of concrete, the writer is glad that Mr. Wiggin has raised the question of the effect of span. Table 8 must be considered as lacking more or less in definite indications, as the arches are assumptions on the part of the writer, but it seems fairly safe to conclude that the change of span has relatively small effect on total quantities. As the span decreases, the volume of concrete in the roof decreases, but as the volume in the columns increases, the total volume remains practically the same. The principal saving, therefore, in using longer spans would be in form work, with the additional advantage of increased capacity in the reservoir.

Comparing Arches Nos. 21 and 30, Mr. Wiggin has called attention to the effect of the size of the pier capital on the average roof thickness. Making the pier capital for Arch No. 30, one-eighty-eighth instead of one-seventy-sixth of the roof area would decrease the average roof thickness from 0.675 to 0.663 ft. This is a decrease of only 2%, whereas the change in average roof thickness due to decrease of span from Arch No. 30 to Arch No. 21 is from 0.675 to 0.618 ft., or about 8 per cent. It appears to the writer, therefore, that in this case the change of span has greater effect on the quantities than the change of size of the pier capital.

As stated by Mr. Wiggin, it is absurd to carry the subject of theoretical economy to the extreme, and there are practical limitations in groined arches as well as in all other construction work. Considering the structure outlined in his paper, the writer would recommend the average economy which ordinarily is used in designing concrete work, for example, such as beams, columns, and retaining walls.

The steel reinforcement for groined arch roofs is a question that is probably discussed each time a new roof is designed. In practice, reinforcement is seldom used, although in certain instances the writer believes it is advisable, such as in the new Baldwin Reservoir for the City of Cleveland, Ohio,* in

* *Engineering News-Record*, November 30, 1922, p. 916.

which the columns and spans are of unusual length. In the Baldwin Reservoir, single, straight, ¾-in. steel rods were placed along the perimeter of each groin adjacent to the crown, and the rods used were of such length that four groins in a group were joined together. Adjacent groups of four groins were not connected. The reinforcement was intended more for construction stresses and construction safety than for working stresses.

In the discussion, attention is called to the use of groined arches in the floors of reservoirs. The writer is not in favor of using groined arches in this manner. Plain floors will be easier to place if the foundations are solid, and they can be designed so as not to involve extra concrete. If the foundations are not solid, the groined arches would be likely to open due to slight settlement and cause very heavy leakage.

The proper concrete mixture for groined arches is a subject for the most careful consideration, and the writer must admit his conservativeness on this question. The decision to use certain proportions does not guarantee a predetermined strength, as the quality and size of the aggregate and other factors are of equal or, perhaps, more importance. If possible, the proportions should be determined from actual tests. In the writer's opinion, the average ultimate compressive strength of the concrete developed in 28 days should not be less than 1 800 lb. per sq. in.

In conclusion, the writer wishes to state again that the various comparisons and approximate formulas discussed in his paper are intended principally as an aid in the design of concrete groined arches, and it is believed that the points noted in the paper and in the thorough discussion by Mr. Wiggin will be of assistance in this special field.

Paper No. 1512

TENTATIVE PLAN FOR THE CONSTRUCTION OF A 780-FOOT ROCK-FILL DAM, ON THE COLORADO RIVER, AT LEES FERRY, ARIZONA

By E. C. La Rue,* M. Am. Soc. C. E.

With Discussion by Messrs. C. R. F. Coutlee, H. B. Muckleston, Edwin H. Warner, F. A. Noetzli, Kirk Bryan, Arthur P. Davis, J. C. Stevens, J. H. Quinton, Ernest H. Baldwin, C. S. Jarvis, Samuel Fortier, L. F. Harza, I. Gutmann, and E. C. La Rue.

Synopsis

It is proposed to build a rock-fill dam in a narrow canyon of the Colorado River by blasting in the canyon walls. The dam described in this paper was designed to raise the water 700 ft. above the bed of the river. Both the height of the dam and the plan suggested for its construction are unique features. The walls of the canyon rise 1 300 ft. above the river, and the width of the canyon at the water surface is 450 ft.

During the past six years, the writer has had in mind the plan herein outlined for the construction of such a dam. There may be a difference of opinion as to the feasibility of the plan as presented. Some engineers may have studied this problem carefully, but to the writer's knowledge no one has ever made the results of his studies available to the Engineering Profession. It is hoped that engineers will present their views in the form of constructive criticism of this paper.

Introduction

In the southwestern part of the United States, the demand for power is increasing rapidly. In California alone, construction plans which call for

* Hydr. Engr., U. S. Geological Survey, Pasadena, Calif.

the expenditure of several hundred million dollars, have been adopted for the development of hydro-electric power. As a result of these plans, the ultimate development of the power resources of the Sierra Nevada and Coast Range Mountains, in the southern part of California, is in sight.

The construction of high rock-fill dams by blasting down the towering canyon walls has been suggested in connection with studies for both power and irrigation development. This paper deals primarily with the practicability of constructing such a dam in the Colorado River. A particular site (Lees Ferry, Ariz.) has been chosen, in order that the discussion might be based on definite dimensions. The paper should not be construed, however, as advocating this or any other specific project.

Colorado River Basin.

General Features.—The Colorado River is formed by the junction of the Green and Grand Rivers in Southeastern Utah. The combined length of the Green and the Colorado is 1 700 miles and the total fall is about 14 000 ft.

The Colorado River and its tributaries drain an area of 244 000 sq. miles. This area comprises the southwestern part of Wyoming, the eastern half of Utah, the western part of Colorado, practically all of Arizona, and small parts of California, Nevada, New Mexico, and Mexico. (Fig. 1.)

The water resources of the Colorado River Basin are enormous. About 14 000 000 acre-ft. of water is wasted annually into the Gulf of California. Practically all this water could be used for irrigation and, in addition, a large amount of hydro-electric power could be developed. In order to utilize fully the water resources of the Colorado River Basin, the flow must be regulated to meet the demands for both irrigation and power. The storage of the flood waters would serve a threefold purpose: Water would be available for irrigation when needed; the possibilities for the development of hydro-electric power would be greatly increased; and with the ravaging floods under control, property on the lower river, exceeding $100 000 000 in value, would be safe.

Storage Reservoir Sites.—A comprehensive plan for the development of the water resources of the Colorado River Basin will undoubtedly call for the utilization of most of the reservoir sites mentioned in Table 1. The locations of these sites are shown on Fig. 1.

Table 1.—Storage Reservoir Sites in the Colorado River Basin.

Name.	Stream.	Height of dam, in feet.*	Capacity, in acre-feet.
Flaming Gorge	Green River, Utah-Wyoming	255	4 720 000
Juniper Canyon	Yampa River, Colorado	200	1 400 000
Ouray	Green River, Utah	300	28 000 000
Kremmling	Grand River, Colorado	230	2 200 000
Dewey	Grand River, Utah	213	2 500 000
Green-Grand	Junction of Green and Grand Rivers, Utah	270	8 600 000
Bluff	San Juan River, Utah	264	2 600 000
Lees Ferry	Colorado and San Juan Rivers, Utah-Arizona	700	50 000 000†
Boulder Canyon	Colorado River, Nevada-Arizona	600	31 600 000

* The figures in this column indicate the elevation of spillway above river bed.
† Estimated.

These storage sites and their use were discussed in the writer's report on the "Colorado River and Its Utilization".* An analysis was made of the records of stream flow, and mass curves indicated that the flow of the Lower Colorado could be equalized if properly located reservoir sites having an aggregate storage capacity of 25 000 000 acre-ft. were utilized. This study also indicated that, if no allowance is made for evaporation from the surface of these reservoirs, a uniform flow of 21 800 sec-ft. could be maintained below the San Juan River. The irrigation of additional lands in the Upper Basin would further reduce the quantity for the uniform flow that might be maintained by storage.

Undeveloped Water Power Between Green River and Boulder Canyon.—In the 670 miles between the Town of Green River, Utah, and Boulder Canyon, Nevada-Arizona, the fall is about 3 350 ft. As this part of the Colorado and that part of Grand River below the elevation of the Town of Green River are in practically a continuous canyon, the use of the water for irrigation within this stretch is impossible; but conditions are favorable for the regulation of flow by storage and for the development of power. The entire regulated flow might profitably be used for the irrigation of extensive areas of arable land below Boulder Canyon.

The data now available indicate that the water power resources of the 670 miles of the river between Green River and Boulder Canyon, may be utilized by developing five projects.

Green-Grand Project.—A 170-ft. dam built on the Colorado River immediately below the mouth of Green River would make possible the development of 110 000 h. p. The capacity of this project for power may be greatly increased when the flow of the Green and Grand Rivers is regulated by additional storage in the upper basin of these streams.

Lees Ferry Project.—By building a dam at Lees Ferry to raise the water 700 ft., 1 000 000 h. p. may be developed.

Marble Canyon Project.—Assuming that the flow of the river is regulated by storage above, it may prove feasible to develop 1 380 000 h. p. between Lees Ferry and the western boundary of the Grand Canyon National Park.

Diamond Creek Project.—Between the western boundary of the Grand Canyon National Park and Diamond Creek, the Colorado River falls 500 ft. This part of the river may be developed by building two dams, each dam to raise the water 250 ft. The capacity of this project would be 830 000 h. p., if the flow of the river is regulated by storage above.

Boulder Canyon Project.—It is assumed that at Boulder Canyon the flow will be re-regulated to meet the demand for water for irrigation. Under this condition, a dam 550 ft. high will make possible the development of 700 000 h. p.

More than 4 000 000 continuous horse-power may be developed between Green River and Boulder Canyon. The aggregate installed capacity of the power plants would probably be more than 5 000 000 h. p.

The Lees Ferry Project

Eight miles above Lees Ferry, Ariz., is a site which has been selected as particularly favorable for both the regulation of flow and the development of

FIG. 1.

power, the possibilities of which will be disclosed by the surveys and investigations now in progress.

Fig. 1 shows the general location of the Lees Ferry project and Figs. 2 and 3 show tentative plans for the storage dam, alternate spillway sites, and the position of the power tunnels and power house. The contours (Fig. 2) were sketched in and are intended only to show roughly the surrounding topog-

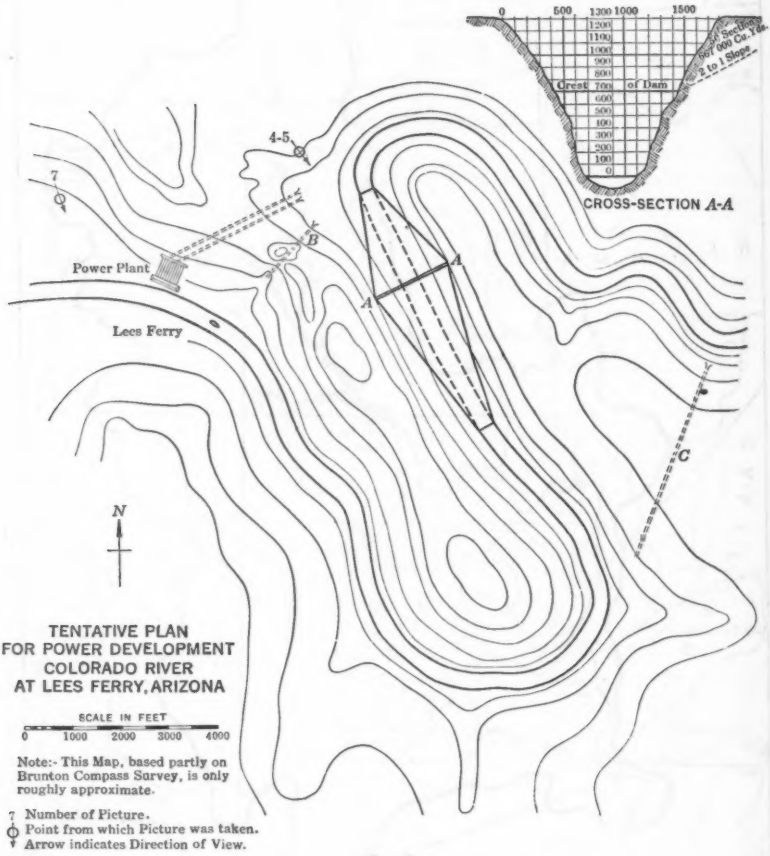

FIG. 2.

raphy. A careful survey will probably show more favorable conditions. The physical features are shown clearly in Figs. 4, 5, 6, and 7. The views can be better understood by referring to Fig. 2, on which is shown the number of the photograph, the point from which it was taken, and an arrow indicating the direction of view.

Present information indicates that to construct a 780-ft. dam at the Lees Ferry site may prove feasible. A dam of this height would form a reservoir with a capacity of about 50 000 000 acre-ft. The maximum back-water would extend up stream nearly to the junction of the Green and Grand Rivers and to within 230 ft. of the elevation of the piers of the railroad bridge near Green River, Utah.

The capacity of the upper 100 ft. of the Lees Ferry Reservoir would be about 20 000 000 acre-ft. Allowing for evaporation from the reservoirs and for the use of water in the upper basin for the irrigation of additional lands, the 20 000 000 acre-ft. of storage capacity may be sufficient to equalize the flow through the canyons of the lower river. With a 100-ft. drawdown, the average head available at Lees Ferry for power would be about 650 ft., and with the flow of the river equalized at this point, power plants in the canyon below could be operated under heads almost equal to the full height of the respective dams. The dam farthest down stream, however, should provide sufficient storage capacity to regulate the flow to conform to the demand for irrigation.

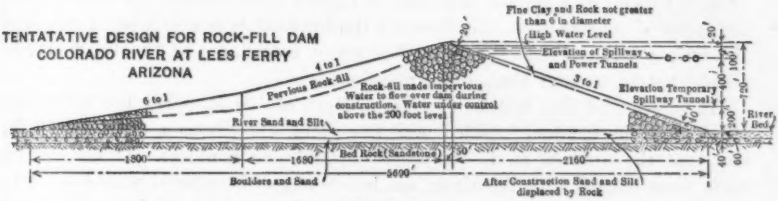

FIG. 3.

Under these conditions, it seems probable that an aggregate effective head of 2 800 ft. may be utilized out of the 3 350 ft. of fall between Green River, Utah, and Boulder Canyon.

The mean annual flow at Lees Ferry has been about 15 000 000 acre-ft., but allowing for the reduction in flow for ultimate irrigation development in the upper basin, this quantity may be reduced to 10 000 000 acre-ft. It may be fifty years before ultimate irrigation development in the upper basin is reached. To assume that a uniform flow of about 19 300 sec-ft. can be maintained at the Lees Ferry site and in the canyons below would seem reasonable.

The depth to bed-rock at the dam site has not been determined, but the writer believes that rock is near the surface in the river channel. When he examined this part of the river in August, 1915, the river was at a very low stage, and down stream about 8 miles from the Lees Ferry dam site, the bed-rock appeared to extend across the channel of the Colorado River at the surface.

At the dam site, the red sandstone walls of the canyon rise 1 300 ft. above the river, and the width of the canyon at the water surface is 450 ft. The course of the river at this point is in the form of the letter "S", thus making two spillway sites available. By constructing tunnels through the bluff, the water may be carried about 3 000 ft. to a forebay and power house which is 6 miles by river from the dam site. The site is easily accessible by automobile

and a railroad could be built at a comparatively low cost, connecting with the nearest railroad point, Flagstaff, Ariz., 133 miles to the south. After considering the conditions at the dam site, the facilities for spillways, site for power house and auxiliary structures, storage capacity above the dam, and the accessibility of the project, the writer believes the Lees Ferry site to be one of the most promising on the Colorado River below the junction of the Green and Grand Rivers.

Should this project be developed, water would be available for irrigation on the lower river for at least a generation to come, and the menace from floods would be removed (except floods from the Gila River).

The conditions favor the construction of a 780-ft. dam of the rock-fill type. (Fig. 3.) Although such a high rock-fill dam has never been constructed, the writer believes that one can be built at this site and made practically watertight at a much less cost than any other type of dam.

Tentative Design for Rock-Fill Dam.—In designing a rock-fill dam for the Lees Ferry site, a slope of 3:1 was used for the up-stream face; for the down-stream face, 6:1 was used to the 300-ft. level, and 4:1 for the remainder. (Fig. 3.) The rock for the dam can be blasted from the canyon walls. With this plan of construction, the slopes of the finished dam would be uneven, but the writer believes that the general slope of both faces of the finished dam should not be greater than those mentioned.

It is assumed that bed-rock lies at a depth of 100 ft. below the bed of the river, that the channel is filled with fine sand and silt to a depth of 60 ft., and that the next 40 ft. is composed of sand and boulders. If the canyon walls were blasted into the river, the heavy mass of material would settle to the level of the boulders assumed to be 60 ft. below the bed of the river, and some of the fine sand and silt would be forced up. Under these conditions, the finished dam would contain 50 000 000 cu. yd. of material. The center 50-ft. section of the dam would contain about 1 000 000 cu. yd.

Prior to construction, the outline for the dam could be plainly marked on the canyon walls. (Fig. 4.) A plan for mining both walls of the canyon could be worked out from detailed topography of the site of the dam. To obtain 500 000 cu. yd. of rock from each wall for the center 50-ft. section of the dam, it would be necessary to blast the walls back on a slope slightly steeper than 2:1 (Fig. 2), and, here, it may be necessary to rehandle some of the material. Up and down stream from the center 50-ft. section of the dam, the walls of the canyon may be blasted from a lower level, and the required quantity of material obtained by blasting back on a much steeper slope. The space occupied by the loose rock in the dam will be about 15% greater than the space occupied by the same material in its natural compact state. If the mines are properly placed in both walls of the canyon, the first shots will blow enough rock into the river to form a dam 250 ft. high, having a gradual slope to the lower toe, more than a mile down stream.

The discharge of the river may be expected to range from 4 000 to 10 000 sec-ft. during the eight months following the flood period. Perhaps 50% of the material in the dam would consist of rock weighing from 1 ton to 1 000 tons. If the unexpected should happen, and a flood of 100 000 sec-ft. should

FIG. 4.—DOWN-STREAM VIEW OF DAM SITE AT LEES FERRY, ARIZ.

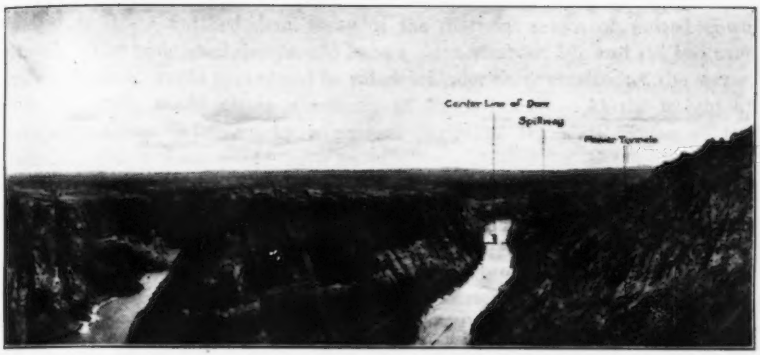

FIG. 5.—PANORAMIC VIEW, LEES FERRY, ARIZ.

FIG. 6.—UP-STREAM VIEW, 1 MILE BELOW DAM, LEES FERRY, ARIZ.

FIG. 7.—VIEW SHOWING SITE OF POWER HOUSE, ETC., LEES FERRY, ARIZ.

pass over the unfinished dam, some of the material might be moved down stream. The unfinished dam would have a slope of about 5% and the bed over which the flood would pass would be rough. Under these conditions, the water, 8 ft. in depth, might attain a velocity of 30 ft. per sec. As the weight of bodies that can be moved by a current varies as the sixth power of the velocity, such a flood would have an enormous ability for destruction. The lighter materials would be carried down stream, and rock that could withstand the force of the water would settle. However, floods which occur outside the normal flood period, last only a few days. To believe that after the flood, the unfinished dam would retain a height of 100 ft. or more above the average low-water level seems more reasonable than that all of it would be carried away. Such a flood might prove to be a blessing in disguise, as that part of the dam remaining would form a solid foundation on which to build the superstructure.

However, flood water should not be permitted to flow over the dam, and it is suggested that no material be blasted into the river until a temporary spillway has been provided 200 ft. above the bed of the river. A spillway tunnel located at *B* (Fig. 2), would be about 3 000 ft. long and could be given a fall of 200 ft. A spillway tunnel, 30 ft. in diameter, with a properly designed entrance, would have approximately the following capacity:

Elevation of water above gate-sill, in feet.	Capacity, in second-feet.
0	0
10	5 000
20	13 500
30	22 500
40	28 500
50	33 700
60	38 200
70	42 000
80	45 000
90	47 400
100	50 000

With the spillway completed and the flood stage passed, the mines may be discharged and about 20 000 000 cu. yd. of rock would be blown into the river. This mass of loose rock would not be water-tight which feature is the most uncertain in the plan here presented.

This mass of rock, weighing about 40 000 000 tons, would displace the fine sand and silt and would tend to form a mud bank immediately up stream from the dam. Such a mud bank would be practically water-tight and, until overtopped, it would cut off the flow of the river. This material might make the rock-fill water-tight to an elevation of 50 to 100 ft. above the bed of the river, and thus form a reservoir having a storage capacity of from 100 000 to 700 000 acre-ft. If the flow of the river was 5 000 sec-ft., the supply of water for irrigation might be cut off for a period of from 10 to 70 days.

Water for the irrigation of more than 400 000 acres of land on the Lower Colorado must be available each month of the year. To cut off the supply of water for the irrigation of these lands, even for a 10-day period, might result in serious damage to crops, and an understanding should be had with the irrigation interests, in order that they may take proper steps to protect the crops should the supply be cut off.

Therefore, unless a temporary spillway is provided at an elevation of 50 ft. above low water, it will be necessary to discharge the mines when the river is in flood so that the storage reservoir above the dam may be quickly filled, and permit the water to flow either through the upper part of the unfinished dam or through a temporary spillway located at the 200-ft. level. The writer believes that the temporary spillway should be located at the 200-ft. level and that the mines should be discharged after the peak of the summer flood, when the discharge has fallen to about 50 000 sec-ft. This feature of the project deserves consideration, and a thorough study of the stream-flow records should be made to determine the proper time for the first discharge of the mines.

Practically all the rock-fill can be blasted into place, thus making it unnecessary to rehandle the material except for finishing a small section at the top of the dam. The 50 000 000 cu. yd. of rock could probably be blasted into place at a cost of 10 cents or less per cubic yard. To determine the quantity of fine material necessary to make the rock-fill water-tight would be difficult, but the writer believes that about 10 000 000 cu. yd. of fine rock, sand, and silt would be required.

The upper face of the dam would be permanently submerged to the 600-ft. level, and, therefore, below this level no protection against wave action is necessary. The water in the reservoir would fluctuate between the 600 and 700-ft. levels. The reservoir would be located in a deep box canyon the circuitous course of which would prevent excessive wave action. (Fig. 3.) On the upper face of the dam, above the 600-ft. level, rock 2 ft. in diameter should probably be placed. This section will be wet and dry periodically and will require care in its construction, if the back-fill is to be kept water-tight.

Making the Rock-Fill Water-Tight.—Several methods have been used in the past to make rock-fill dams water-tight, but most of these methods appear to be unsatisfactory when applied to such a high dam.

A concrete core-wall extending to bed-rock is often used. If this plan were adopted at the Lees Ferry dam site, it would be necessary to excavate the river channel to bed-rock. To take care of the flood water during the period when the core-wall is being built from bed-rock to the former water surface, would be both hazardous and expensive. For such a high dam there would be danger of the core-wall becoming fractured on account of uneven forces being exerted by the rock-fill.

A steel core, having a concrete base, would be even more objectionable than a concrete core, for besides requiring a concrete facing to prolong its life, it would have all the objectionable features of the concrete core.

The rock-fill might be made water-tight by lining the up-stream face of the dam with concrete, but it would be necessary either to carry this concrete facing to bed-rock or to provide an impervious base for the dam with a series

of cut-off walls. Otherwise, the water would pass under the concrete facing and undermine the dam. In addition to these objectionable features, the settlement of the rock-fill would make it almost impossible to prevent the concrete facing from becoming fractured.

The writer believes that, with the river under control, the rock-fill can be made water-tight by sluicing fine material into the dam.

The discharge of the river ranges from 4 000 to 10 000 sec-ft. after the flood period. This quantity of water might find its way through the rock-fill. At this stage of construction, every attention should be given to the work of making the rock-fill water-tight. It would be necessary to place fine material on the upper face and perhaps as far down stream as the center of the finished dam. This material should be graded in size from that which would pass through a 1-in. to a 6-in. mesh. On the right bank of the river, a few hundred feet up stream from the upper toe of the dam, there is a talus which could be moved to the dam at a low cost. The back-water above the dam might have a depth of from 75 to 100 ft. and would extend up the river a distance of at least 25 miles.

Assuming that the rock-fill rises 250 ft. above the bed of the river, and that there is 100 ft. of water above the dam, the flow of water through the dam would be as follows: The water would rush through the open spaces between the large rocks, flow through the spaces between the smaller rocks, percolate through the sand, and seep through the clay or fine silt. The rush of water through the spaces between the large rocks would be partly stopped by the coarser material, that is, the rock 6 in. in diameter; and the flow through the spaces between the smaller rocks would be partly stopped by the finer material, that is, rock that would pass the 1, 2, 3, or 4-in. mesh. Large quantities of sand may then be deposited on the upper face of the dam. Due to the flow of water under high pressure, this sand would be carried into the dam. The deposit of fine clay or silt on the up-stream face and on top of the dam should produce a practically water-tight structure. Owing to the enormous pressure, water would always seep through the dam, but probably not in quantities sufficient to cause erosion.

When, in 1915, the writer made a trip by boat through 150 miles of the canyon of the Colorado River between Hite, Utah, and Lees Ferry, Ariz., large silt deposits at the mouth of Navajo Creek were observed. This creek joins the Colorado from the south, at a point about 18 miles up stream from the site of the Lees Ferry dam. Large silt deposits also were observed at many other points in the canyon below the mouth of San Juan River. These deposits could be located before they are covered with the back-water, and as the water reached the respective deposits, the material could be loaded on barges by dipper or suction dredgers. It might prove more economical, however, to place rock crushers on the plateau above the dam and transport the crushed material to the dam by chutes. It is thus seen that there is plenty of accessible material for use in the final process of making the rock-fill water-tight.

When the rock-fill becomes water-tight and the reservoir fills, the water may percolate through the 40-ft. layer of sand and boulders. (Fig. 3.) This water would be forced to travel a distance of about 5 700 ft. The indicated

hydraulic gradient is about 1:8, and the writer believes that the frictional resistance to the passage of water through the 40-ft. layer of sand and boulders would be sufficient to consume the head of 700 ft. before the lower toe of the dam is reached, in which case, the velocity of the percolating water near the lower toe of the dam would not erode the foundation. Under these conditions, the dam as designed would be safe against blow-outs caused by the upward hydrostatic pressure of the percolating water on its base.

It is said that the silt-laden waters of the Colorado would be sufficient to tighten the dam. This silt, however, would be deposited at the head of the back-water and not at the dam, which condition favors the completed project. With reservoir full, the back-water would extend up every side canyon and tributary of the Colorado, and would probably extend up the San Juan River, a distance of 80 miles or more. The San Juan, which carries a large quantity of silt would have its own stilling basin and, perhaps, 100 years would pass before the silt would reach the canyon of the Colorado. As each side canyon would have its own stilling basin, the water in the main canyon of the Colorado above the dam would remain practically clear. This is important when it is considered that the water is to be used for the development of power.

As it is proposed to blast about 20 000 000 cu. yd. of rock into the river channel with the first discharge of the mines, arch action may result when this enormous quantity of material falls into the canyon, thus leaving a large open space within the proposed dam. Although such arch action is only a remote possibility, it might be advisable to discharge the mines in both walls of the canyon at the same instant, so that much of the material may meet over the river channel and fall vertically. Perhaps better results can be obtained by discharging the mines in one wall, after those in the other wall, but the writer believes it is impossible to determine just how the rock will fall when the mines are discharged.

Care of Water During Construction.—The writer believes it unnecessary to have the river under control until the dam is raised to an elevation 250 ft. or more above the bed of the river. If the mines were discharged immediately after the flood period has passed, at least eight months would elapse under normal conditions before the river would again be at flood stage. During these eight months, it is expected that the upper face of the dam can be raised 100 ft., or to an elevation of 350 ft. above the bed of the river. The storage capacity of the reservoir between an elevation of 200 and 350 ft. is about 8 000 000 acre-ft.

The writer has described* the flood of 1917, during which the peak at Lees Ferry was about 147 000 sec-ft., one of the highest floods of record originating above that site. An analysis of the records of daily discharge for this flood period shows that the water level in the Lees Ferry Reservoir would have been raised from an elevation of 215 ft. to an elevation of 332 ft. above the bed of the river. The accumulated storage above the 200-ft. level would have been about 7 300 000 acre-ft. and the total volume discharged through the temporary spillway would have been nearly 7 500 000 acre-ft. It is seen, therefore, that in order to prevent such a flood overtopping the unfinished

* *Engineering News-Record*, March 6th, 1919.

dam, it would have been necessary to raise the dam at least 332 ft. above the bed of the river. For the plan of construction herein presented, the writer believes that the most dangerous period would be that during which the dam is being raised from the 200 to the 350-ft. level. During this period, it may be necessary to take care of a summer flood such as that which occurred in 1917.

The water level in the reservoir during construction might be controlled most economically and efficiently by one temporary spillway, at the 200-ft. level, controlled by a Johnson valve having a capacity of 60 000 sec-ft. under a static head of 100 ft. As this spillway is to be used only during construction, it would not be necessary to provide slide-gates so that the Johnson valve may be unwatered for inspection and repairs. If a summer flood, such as that which occurred in 1917, must be taken care of when the dam is nearing the 300-ft. level, the temporary spillway will be taxed to its maximum capacity of 60 000 sec-ft. As the dam is raised above the 300-ft. level, the storage capacity of the reservoir becomes much greater, so that a spillway capacity of less than 60 000 sec-ft. would be required. Under this plan, the dam could be built to its full height without fear of its being overtopped by a flood during construction.

The tunnels leading to the power house may be located at the 600-ft. level. (Fig. 3.) As this paper deals primarily with the design of a rock-fill dam, no attempt will be made to determine the most feasible location for the power tunnels.

The summer floods are caused by the melting snows in Colorado, Utah, and Wyoming. From the records of precipitation, the volume of the coming summer flood can be determined with fair accuracy 60 days in advance. A permanent spillway should be provided at the 600-ft. level so that the water level in the reservoir may be drawn down to provide sufficient capacity to take care of a flood much greater than any heretofore recorded.

Those in charge of the operation of the reservoir would be more concerned with the volume of run-off than with the magnitude of the flood peak. The quantity of snow in the upper basin would indicate whether the expected run-off would be high, low, or average in volume. An extended period of high temperatures, accompanied by a warm rain or "chinook" wind, would cause a flood of great magnitude, but of short duration. It would be impossible to predict such conditions 60 days in advance, but a study of the run-off records for the past 20 years would afford a fairly accurate basis for a prediction as to the time the summer flood may be expected.

Power During Construction.—As coal is abundant within 15 miles from the site, a steam plant could be built to furnish power during construction. After the dam has been raised above the 200-ft. level and the water is passing through the temporary spillway, power may be had by constructing a hydro-electric plant at the outlet of this tunnel.

Conclusions

1.—At the site of the Lees Ferry Dam, the canyon is narrow and the red sandstone is of good quality. These conditions favor the construction of a

rock-fill dam. It seems probable that practically all of the 50 000 000 cu. yd. of rock for the fill can be blasted into place. However, it will be necessary, or at least advisable, to resort to the hand-and-derrick method in placing a part of the rock in the section of the dam above the 600-ft. level. The slopes of the finished dam are not expected to conform exactly with those shown on Fig. 3, but it is the writer's opinion that the average slope should not be steeper.

2.—Owing to the favorable conditions at the site of the dam, the writer believes it entirely feasible to raise the dam to the 250-ft. level with the first discharge of the mines. The quantity of material required to form a dam 250 ft. high depends on the depth to the layer of boulders and the depth to bed-rock. It would be advisable, therefore, to test the river channel for bed-rock by diamond drill borings.

3.—It would not be necessary to by-pass the flood water until the dam has been raised to an elevation of 200 ft. above the bed of the river, except that provision must be made to meet the demand for water for irrigation.

4.—Provision should be made to control the water level in the reservoir above an elevation of 200 ft., in order to facilitate the sluicing of fine material into the rock-fill to make it water-tight.

5.—Flood water should not be permitted to overtop the dam after it has been built higher than 200 ft. above the river bed.

6.—A permanent spillway should be provided at the 600-ft. level.

7.—The raw materials necessary for the construction of a rock-fill dam are conveniently situated.

8.—In this project, it is planned to do on a large scale what has often been successfully accomplished on a smaller scale. The writer believes the most uncertain feature of the project is the work of making the rock-fill water-tight. If the seepage through the dam is sufficient to cause erosion, it would not be very expensive, considering the magnitude of the project, to blast in the canyon walls and produce a 6:1 slope from the crest of the dam to the lower toe.

9.—The writer believes that a rock-fill dam properly constructed would be fully as safe as a concrete dam. To the design herein presented for a rock-fill dam, the unit stresses developed in the foundation and abutment walls are low and need be given minor consideration. This type of dam, however, may be subject to failure due to a blow-out which might be caused by the upward hydrostatic pressure of the water percolating under the foundation. The writer believes that the rock-fill dam described in this paper would be safe against blow-outs or erosion. Should erosion occur, no doubt the trouble could be remedied long before there was any real danger of the dam failing.

Should either the rock-fill or a concrete dam be overtopped by a flood, the damage might be sufficient to cause failure. A flood passing over the top of the rock-fill dam would cause at least a partial failure of the dam. The seriousness of the damage would depend on the magnitude and duration of the flood.

Because the capacity of the reservoir is enormous, it is a comparatively simple matter to provide adequate spillway capacity, and the chances of a dam being over-topped by a flood are remote.

10.—A concrete dam built at the Lees Ferry site to raise the water 700 ft. above the bed of the river would have a volume of about 5 400 000 cu. yd. and would probably cost, including spillway structures, about $50 000 000. It is difficult to estimate the cost of a dam of the rock-fill type, but a liberal estimate indicates that it would be little more than half that of the concrete dam.

DISCUSSION

C. R. F. COUTLEE,* M. AM. SOC. C. E. (by letter).—Rock-fill dams are perhaps the most useful appliances in engineering, now that water power has become such a prominent branch of that science. They have been used in India for a long time, the up-stream face being staunched by depositing, first, stone of one-man size, then macadam size, and, finally, sand. Two parallel rock-fills with an earth center, as used at Panama, is a splendid arrangement.

At Kenora, Ont., Canada, there is a rock-fill dam with sluiceways closed by movable stop-logs. It was built by the late Sir John Kennedy, M. Am. Soc. C. E., 30 years ago, the granite rock being deposited in the rapids without particular care. The up-stream face is neither paved nor staunched, and the leakage has remained about constant. The slope through the dam extends from the water surface above to about 1 ft. higher than the surface of the water below. The head is 18 or 20 ft., the slopes are 1:1, and the width 3 ft. above water is 6 ft.

The Georgian Bay Canal Project, Ottawa River, included many large rock-fills which are described in the report for 1908 of the Public Works Department of Canada. In connection with the Ottawa River storage, several rock-fill dams were built from 1909 to 1912.

At the foot of Quinze Lake, the dam is more than 1 mile long and 45 ft. high in middle channel. The embankment was made from each side and closed in mid-stream with a flow of 5 000 sec-ft. running. Large rocks were carried down stream at first, but they soon came to rest and others jammed against them, until gradually the fill grew up stream. Part of the dam, more than 30 ft. high, was deposited on a swamp. The slopes are 1.5:1, with a width of 10 ft. at 5 ft. above full reservoir.

At Kipawa River, at the north end of the lake, a rock-fill was deposited across a crevice in the granite about 100 ft. wide, through which 1 000 sec-ft. poured in a rapid. At the south end of Kipawa Lake, another rock-fill, 500 ft. long, was deposited on bare rock. No attempt was made to staunch any of these dams. At the north end of Kipawa Lake, the leakage is 300 sec-ft., and at the south end about 200 sec-ft., the maximum head approximating 15 ft.

At the Timiskaming Dam, four concrete sluiceways were scoured under during the spring flood of 1912, and the piers settled down into a sand pocket. Satisfactory repairs were made by filling in the gap with rock. The depth was 25 ft. and the head about 15 ft. Down stream from this dam, a flow of 70 000 sec-ft. scoured out a hard boulder bottom to a depth of 20 ft. below the sill, for a width of 400 ft. This was filled with 30 000 cu. yd. of loose rock, into which the next high flow scoured 15 ft. in depth. Loose rock was again used for filling, and further scouring has not taken place. Descriptions of these works are given in the Ottawa River Storage Reports of the Public Works Department of Canada for 1913 and 1915, which, although out of print, are available in libraries. In constructing the branch of the Canadian

* Ottawa, Ont., Canada.

Pacific Railway from Toronto north to Sudbury, Ont., rock embankments were made to sink into muskeg swamps with considerable certainty as to alignment.

A rock-fill becomes part of the geology of the country, it will not overturn nor slide on its base, and it will stand overtopping for some time. It is very strong, but leaky. To staunch the face, the voids should be gradually reduced with stone decreasing to macadam size and then a covering of earth should be applied at slope of from 3 : 1 to 7 : 1. Brush mattresses are not desirable for staunching, as they bridge voids and eventually break suddenly. At Frank, Alberta, Canada, the great rock slide, 2 miles long and 2 miles wide, occupied the whole bed of the middle fork of the Old Man River. Without gathering much head, the small river, however, has been able to seep through.

A great rock-fill dam might be constructed across the St. Lawrence River, near Rivière du Loup, Que., Canada, requiring 70 000 000 cu. yd., which could be deposited after twin locks, similar to those at Panama, had been built in Hare Island. The sluiceways to pass 800 000 sec-ft. could also be constructed in the dry before any rock was deposited. This would bar out the tide, leaving the water of the upper river fresh, with a current in the outward direction only. There would be no more tidal fluctuation or choking by tide-borne ice, and a 40-ft. depth, without flooding, would be secured. In a similar manner, a rock-fill, 400 or 500 ft. wide on top, could be built across the Hudson River between New York and New Jersey, which would keep the river at a constant level as far as Albany, N. Y.

H. B. Muckleston,* M. Am. Soc. C. E. (by letter).—This paper describes a proposal to dam the Colorado River by creating artificially an enormous landslip from the canyon walls. Except for the artificial feature, the proposal is not without precedent.

The same thing occurred naturally in 1893 on the Birahi-Ganga, a small stream in India. In this case, the dam was about 900 ft. high, 11 000 ft. wide at the base, and 2 000 ft. wide at the top. The catchment area above the dam was small, about 90 sq. miles, so that the discharge cannot have been very great. Nevertheless, the dam went out as soon as it was topped.

In view of the author's proposals for staunching his dam, it is interesting to learn that the Gohna Lake Dam referred to, leaked 350 sec-ft., long before it was topped. A full account of this failure has been published.†

Edwin H. Warner,‡ M. Am. Soc. C. E. (by letter).—The author presents a plan for a rock-fill dam 780 ft. high and greater in magnitude than any dam of which there is a record. The type proposed is archaic, developed when low first cost was a necessity, which necessity does not exist in the case under consideration.

The profile, Fig. 3, is conservative; the notation on it "rock-fill made impervious" is reminiscent of "let there be light and there was light". With this

‡ Cons. Engr., San Francisco, Calif.

notation in effect, and the author's statement that there shall be no overtopping of the dam by flood waters after the dam is completed, it is not apparent why the toe should be carried 1 mile down stream. The profiles of rock-fill dams illustrated in the "Design and Construction of Dams", by Edward Wegmann, M. Am. Soc. C. E., show no such exaggeration of the down-stream slope.

The author's first step in construction is to drop 1 000 000 cu. yd. into the bed of the stream, making a dam 250 ft. high, "this will settle 60 ft. through sand and silt which will be forced up". The probability that this settlement will occur does not seem great. Much greater, however, is the probability that, as he says, a flood of 100 000 sec-ft. will strew his rock down stream leaving a dam 100 ft. high; the "blessing in disguise" part of the operation in "leaving a solid foundation on which to build" seems somewhat problematical both as to the "blessing" and the "solid foundation". The next step is dropping 20 000 000 cu. yd. in one shot, on top of the first 1 000 000 cu. yd., thus forming "a mud bank immediately up stream" and cutting off the irrigator's supply for "from 10 to 70 days" until the mud bank is overtopped and washed away. The author states that this "might result in serious damage to the crops, and an understanding should be had with the irrigation interests, in order that they may take proper steps to protect the crops". He does not suggest an arrangement; it could take two forms, namely, the purchase of the crops on 400 000 acres at a cost not much in excess of his estimate of the cost of a rock-fill dam, or supplying water from some other source. Neither of these alternatives seems to be quite practicable, so, perhaps, it is best to be content with the possibility that the "bud bank" will not form, or, if it does, it will not make the complete closure suspected of it.

The author's estimate of 10 cents per cubic yard for blasting 50 000 000 cu. yd., seems to be low when viewed from the cost of explosives alone, and his expectation of landing his rock where he wants it, without rehandling, is negatived by his later statement that "it is impossible to determine just how the rock will fall".

The author believes the dam "can be made water-tight", and states that "there will always be seepage through the dam". To secure water-tightness, he assumes that the graded material, later introduced, will find its appointed place in a structure extending 1½ miles along the river. Perhaps it will; who knows?

The author concludes that the dam will cost little more than half that of a concrete dam, the cost of which he places at $50 000 000. Having assigned $5 000 000 as the cost of the rock-fill, it would be of interest to know what items enter into the remaining $20 000 000.

As a final, or, perhaps, more properly, first point in the matter of the author's design and construction methods, there is nothing advanced to satisfy the bond-buyer's engineer, who is obsessed by a curiosity as to what is to be done with the money his people are asked to furnish; he insists on facts and, at times, declares he can furnish his own opinions, which, being his own, satisfy him. That his opinion would be unfavorable to a rock-fill dam, 780 ft. high, is certain, even conceding as does the writer, that water-tightness is not, beyond reasonable limits, an absolute necessity.

His opinion would likewise be unfavorable to a concrete dam of similar height, as the unit stresses in the concrete would exceed the present limits of good practice. The only dam that will meet his approval is a gravity type, the lower section of which will be mammoth rubble laid in cement mortar and carried up to a point where concrete can be safely used. The author's splendid monograph "Colorado River and Its Utilization",* furnishes data which point to a lesser height of dam than that proposed in this paper.

The mean annual flow of the Colorado at Lees Ferry is 15 000 000 acre-ft., but in order to satisfy fully all irrigation needs, 13 000 000 acre-ft. are required. The storage of 25 000 000 acre-ft. will give proper regulation and, with a dam approximately 450 ft. high, 800 000 h. p. can be developed.

The value of property below Lees Ferry makes imperative the adoption of a dam of the gravity type, because it is the only type which will have the approval of the farmer, the bond-buyer's engineer, and the Federal and State regulatory bodies. The writer holds firmly to the opinion that an arch dam can be designed and built, which will be as secure against failure as the gravity dam, but consideration of this type is precluded by the fact that agreement in this opinion is not to be had from the several parties at interest.

If the author finds less constructive criticism in the foregoing than he asks for, he may find contentment in this, that both he and the writer are dealing largely in opinions on a matter which greatly transcends present knowledge; hence, each may hold to his own without undue prejudice.

F. A. Noetzli,† Assoc. M. Am. Soc. C. E. (by letter).—Hydraulic engineers of the West are keenly interested in the deliberations of the Colorado River Commission which, under the leadership of Herbert Hoover, M. Am. Soc. C. E., has accomplished a great deal toward smoothing out the conflicting interests of the various border States interested in the control and utilization of the waters of the Colorado River. In view of the fact that, by providing adequate reservoirs for storing the flood waters of the river at the various excellent reservoir sites on the main river and its tributaries, sufficient water appears to be available to satisfy, in every State concerned, all reasonable claims for irrigation and power for generations to come, it is to be hoped that the Colorado River Commission will soon be successful in initiating the construction of a large dam on this river.

At present, about 14 000 000 acre-ft. of water, out of an average of 16 000 000 acre-ft., is wasted annually into the Gulf of California. This would be enough water to irrigate at least 3 000 000 acres of land in addition to the area already irrigated from the river. According to the author, "more than 4 000 000 continuous horse-power may be developed between Green River and Boulder Canyon." Such figures should convince one that most of the present quibbling, with regard to sacrificing the rights of certain States for the benefit of others, has few engineering facts on which to rely.

Mr. La Rue's excellent paper will be welcomed by many engineers, as it affords an opportunity to discuss the feasibility of a large dam on the Colorado River. The thorough investigation of the whole project, made by the U. S.

* Published as *Water Supply Paper No. 395*, by the U. S. Geological Survey.
† Chf. Engr., Bissell & Sinnicks, San Francisco, Calif.

Reclamation Service, and more particularly the surveys and borings at the Boulder Canyon Dam site, would appear to have furnished sufficient information to warrant the conclusion that the construction of a high dam across the Colorado River is feasible.

The author suggests the construction of a rock-fill dam by blasting down the canyon walls. In order that the discussion might be based on definite dimensions, he chose the Lees Ferry site, without, however, advocating this or any other specific project.

The suggestion of blasting enormous masses of rock from both sides of the canyon walls is fascinating, but it might prove to be a dangerous experiment on a stupendous scale. There exists no precedent on which to rely. All the evidence that may be gathered from past experience with rock-fill dams would indicate an almost certain failure. The writer is unable to agree with the statement of Mr. La Rue, that (in case of a flood of 100 000 sec-ft. passing over the dam to a depth of 8 ft.), "* * * to believe that, after the flood, the unfinished dam would retain a height of 100 ft. or more above the average low-water level, seems more reasonable than that all of it would be carried away. * * *" In the past, whenever water has overtopped a rock-fill dam for 1 ft., or even less, the dam almost invariably was destroyed. The erosion, which may be assumed to have started at the crest, increased the depth and, therefore, the velocity of the flowing water. Since, as the author states, "* * * weight of bodies that can be moved by a current varies as the sixth power of the velocity * * *", the erosive action of the water overtopping a rock-fill dam increases at a tremendous rate, and soon will move also the largest sized rocks, inasmuch as the waters in the reservoir are discharged, in addition to the flood flow that started the failure. Fig. 8 is a view from the new Lower Otay Dam, down the canyon through which the waters passed, that, in 1916, destroyed the former rock-fill dam. The photograph was taken by the writer early in 1922 and clearly shows the lighter colors of the deeper parts of the canyon, the side walls of which, for miles, were stripped of every loose particle, down to smooth solid rock. The force of the water will be appreciated from such a view. From a description of the failure of the Lower Otay Dam,* it appears that the reservoir of 40 000 acre-ft. capacity was emptied in 2½ hours. This corresponds to an average flow of nearly 200 000 sec-ft. for 2½ hours. In addition, the run-off from the water-shed amounted to about 35 000 sec-ft. The maximum flood peak was, therefore, probably in excess of 300 000 sec-ft., and the water rushed down the canyon with an average velocity of about 18 ft. per sec. Referring again to the possibility of the Lees Ferry dam being overtopped during construction to a depth of 8 ft. by an unexpected flood of 100 000 sec-ft., it appears doubtful if more than perhaps a few of the largest blocks of the dam would stay within the area of the foundation.

Assuming, however, that the unfinished dam would retain a height of 100 ft. after the flood, it may be well to consider also the effect of the water that would be released from the reservoir between the 100 and 250-ft. level The reservoir capacity between these two levels is several million acre-feet, and

* U. S. Geological Survey, *Water Supply Paper No. 426*, p. 25.

FIG. 8.—VIEW DOWN CANYON FROM NEW LOWER OTAY DAM.

most of this water would be released during the first day, producing, with the assumed flow of 100 000 sec-ft., a flood peak, below the dam, of probably more than 1 000 000 sec-ft. The effect of such a flow on the Imperial Valley and the bottom-lands along the Lower Colorado River would be disastrous.

However, it might perhaps be possible to devise a program of construction by which the water would be prevented from overtopping the dam. The question is then narrowed down to the problem of making the dam water-tight during construction, as well as afterward.

Mr. La Rue suggests blasting about 20 000 000 cu. yd. of rock into the river channel with the first discharge of mines located on both sides of the canyon. It hardly can be assumed that this large quantity of rock would settle and spread evenly across the whole river, so as to form a more or less level barrier about 250 ft. in height, which would be the object of this first operation. At the 250-ft. level, the canyon is about 600 ft. wide, and, unless a great quantity of excess powder is used, the blasted rock would probably slide down the sides of the canyon, instead of being hurled a distance between 300 and 700 ft., measured horizontally, to the location where the designer of the dam would like it to drop. The danger evidently exists of a continuous low channel being formed approximately along the axis of the canyon through which the water might escape and destroy the dam before the level in the reservoir had reached the spillway tunnel. A rock-fill dam of the dimensions suggested by the author would no doubt be stable if it was possible to make the dam water-tight, or at least so to reduce the velocity of water percolating through the dam that it would not start erosion and blow-outs.

Past experience with earth and rock-fill dams has shown that, in general, for dams of considerable height, this is possible only by lining the up-stream face, or by providing a water-tight membrane, such as a concrete or steel sheet core-wall, or a puddle of clayey material, etc.

The author believes that "with the river under control, the rock-fill can be made water-tight by sluicing fine material into the dam. * * *" The method proposed is ingenious. However, a combination of unforeseen conditions, such as arching of the loose material within the dam, and consequent abrupt and uneven settlements from the weight of the added rock in the building of the dam, might rupture the originally water-tight sand and silt cover and a blow-out might follow with disastrous consequences. The Colorado River silt is remarkably water-tight even in layers of a few inches, if the silt is precipitated from still or slowly moving water. However, if the water attains a velocity of 3 ft. per sec. or more, erosion takes place with great rapidity. Such action might occur if a silt membrane, on the up-stream face of the proposed dam, was ruptured by abrupt settlements within the dam.

Furthermore, it must be considered that, even if it should be possible, by sluicing, to make the dam water-tight for a working head of, say, 200 or 300 ft., the possibility still remains of flow and erosion starting when the water level in the reservoir would rise 600 or 700 ft. above the stream bed. The water pressure at the bottom of the full reservoir would be 43 700 lb. per sq. ft., or

about 300 lb. per sq. in. Such a pressure is considered by conservative engineers as the limit for good concrete in masonry dams, and probably few designers would rely on a layer of wet sand and silt to sustain safely such load.

It would seem, therefore, that the construction of a rock-fill dam on the Colorado River involves a number of rather doubtful features which, during the construction of the dam, would hardly be conducive to sound sleep on the part of the responsible engineer, or the people living below the dam.

In his report to Congress, Arthur P. Davis, Past-President, Am. Soc. C. E., Director of the Reclamation Service, has demonstrated that the construction of a masonry dam on the Colorado River is safe and feasible. Hardly any dangers to life and property on the Lower Colorado River are involved in the construction of a masonry dam, and the final designs may show such a structure less costly than a rock-fill dam.

The problem to be solved, therefore, is at which of the various sites should such a masonry dam be built? Under present conditions, such a dam has to serve three purposes: Flood control, irrigation, and the development of hydro-electric power.

Flood control of the Lower Colorado River is urgently needed. The great snowfall of the winter of 1921-22, over the drainage area of the river, may produce at some time in the future exactly the dangerous conditions of which the inhabitants of the Imperial Valley are afraid and which such a dam would almost completely eliminate.

Even by permitting the upper States all the freedom desired in the irrigation of any or all of their land that may be entitled to it or that is susceptible of irrigation from this source of supply, enough water would still remain to irrigate 1 000 000 or 2 000 000 acres of additional land in Arizona, California, and Mexico.

Between 500 000 and 1 000 000 hydro-electric horse-power may be developed economically as a by-product. This is more than the market may possibly absorb for many years within economical distance of distribution. According to the author's figures there are, in addition, more than 4 000 000 h. p. capable of development between Green River and Boulder Canyon, enough for generations to come. In view of these facts, it is to be hoped that the various States concerned will soon come together for united action and empower the Federal Government to proceed with the construction of a dam on the Colorado River. The embracing of a maximum part of the water-shed to afford the greatest possible protection from floods, the closer proximity to the large area of irrigable lands, and the closeness to the market for power, all favor the building of a dam at the Boulder Canyon site. After this dam is built, possibly the experiment of constructing a rock-fill dam at Lees Ferry may be undertaken, as suggested by the author. If this construction was undertaken when the Boulder Canyon Reservoir was purposely nearly empty, no great damage might occur if the Lees Ferry rock-fill dam should suffer a blow-out during construction.

The writer is particularly interested in the problems of the Colorado River for the reason that he believes he has solved in part what might be called the problem of the Lower Colorado River below Boulder Canyon. To the present

time, it was believed by many engineers who investigated the lower course of the river, that it was not economically feasible to build a high dam across the river for power purposes. The reason for the negative result of these investigations lies probably in the fact that bed-rock, at the deepest point in the river channel, is more than 100 ft. below the present stream bed. Furthermore, the flow in the river is seldom less than 4 000 sec-ft., and floods of 150 000 to 200 000 sec-ft. may be expected almost every year.

About 5 miles above Parker, Ariz., the solid rock banks on both sides of the Colorado rise about 100 to 120 ft. above the river bed and are 600 to 700 ft. apart. Through the protruding rock hills on the Arizona side, it is proposed to cut a channel about 250 ft. wide, somewhat lower than the present river bed, and, by means of a coffer-dam, to divert the flow of the river during the construction of an earth and rock-fill dam across the main river channel. After the main dam has been completed to the crest, and a spillway of 200 000 sec-ft. capacity is excavated at a favorable location on the California side of the river, the temporary diversion channel may be closed by a concrete arch dam, at the foot of which the power-house might be built. The main dam, which would be about 100 ft. high, would be of the earth and rock-fill type with a concrete core-wall reaching to bed-rock or to a double row of sheet-piling to prevent percolation through the dam.

With a load factor of 70% and the quantity of stored water available between the sill of the spillway and the crest of the 15-ft. gates on top of the spillway, about 100 000 h. p. could be developed. The remainder of the reservoir is thereby assumed to be silted up. The intake to the turbines will be through the arch dam, thus affording a minimum cost of installation and a maximum degree of efficiency for operation. At the tail-race of the power plant, a part of the water discharged by the turbines may be taken in a canal and used for the irrigation of about 120 000 acres of land a short distance below the dam. Complete plans for the irrigation of this land were prepared some time ago by the U. S. Indian Service.

The temporary diversion channel would require the excavation of about 1 000 000 cu. yd. of rock, of which a part might be used in the construction of the main dam.

Thus, by the somewhat unusual method of diverting a mighty river into a new channel, then building, without any undue risks, a dam across the main channel, and closing afterward the temporary diversion canyon by a concrete arch dam, under the most favorable conditions as to rock foundation and side abutments, a safe and economical solution, in part, of the problem of the Lower Colorado River is effected.

It is of further interest to note that the proposed reservoir near Parker would afford an excellent opportunity for temporary flood control for Imperial Valley during the construction of the Boulder Canyon Dam. The time required for building the Boulder Canyon Dam may be 10 years, while the dam at Parker could be constructed within less than 2 years. The capacity of the Parker Reservoir is about 1 500 000 acre-ft., and the silt deposits from the river may reduce this capacity by about 100 000 acre-ft. per year. As the dam will

be used later mainly for creating head for the power plant, the silting process of the reservoir is of minor importance.

KIRK BRYAN,* ESQ. (by letter).†—During the extensive surveys of the Colorado River by the U. S. Geological Survey in 1921, the writer was detailed to conduct geological work in the vicinity of Lees Ferry. The results of this work, in so far as they affect the building of a dam at Lees Ferry, are presented herewith. The paper by Mr. La Rue has raised definite questions in the solution of which the geologic facts are pertinent.

Rocks Involved.—The rocks in the vicinity of Lees Ferry are sedimentary in character and form great beds of like material that are persistent in composition over large areas. The character of these rocks is given in Table 2 and their distribution is shown on the geologic map, Fig. 9, from which also the reader will be able to locate various features of the topography which are discussed subsequently. Fig. 10 shows the formations from the Kaibab limestone to the top of the Jurassic sandstone with the characteristic topography of each formation.

TABLE 2.

	General Section of Rocks near Lees Ferry.	Feet.
Jurassic.....	Brown thin bedded sandstones and shales. (Wingate and Navajo of Gregory). Massive tangentially cross-bedded red to buff sandstones. No parting visible at the center, but upper half has lenses of dense gray limestone 6 in. to 3 ft. thick at intervals and near the top, nodules of limonite the size of peas are common. In the Vermilion Cliffs the upper half is distinctly lighter in color.	? 1 100-1 200
Triassic.....	Chinle formation (Upper Triassic). Blue, green, and red shales; white, gray, purple, and red sandstones; and cherty limestones. Upper part of Chinle formation consists of heavy bedded sandstones and red shales. Lower part contains fossil wood.	1 000±
	Shinarump conglomerate (Upper Triassic?). Gray conglomerate with lenses of sandstone and shale; much fossil wood.	0-40
	Unconformity.	
	Moenkopi formation (Lower Triassic). Red sandy shales and thin bedded sandstones with seams of gypsum. In places has beds of red and gray sandstone 2 to 6 ft. thick, and in one locality 12 ft. of gypsiferous limestone. Base, generally, 1 to 10 ft. of chert conglomerate.	500±
	Unconformity.	
Permian.....	Kaibab limestone. Yellow limestone with numerous more or less rounded nodules of chert.	250
	Coconino sandstone. Gray cross bedded massive sandstone.	300
	Unconformity (?) Hermit (?) shale. Red shale and sandstone.	
	Unconformity (?). (Not observed).	
Permian (?) and Pennsylvanian.....	Supai formation. Red shale with beds of blue limestone.	500+ observed

Of these formations, the sandstones of the Jurassic Age form high and conspicuous cliffs in Echo Cliffs, Vermilion Cliffs, and Glen Canyon. In many places also, the almost sheer cliff is continued downward in the ledges of red

sandstone and intervening shales of the upper part of the Chinle formation. In general, however, the Chinle formation forms ragged badlands or is concealed below the débris from the overlying cliffs. The Shinarump conglomerate commonly forms a cliff and sustains a platform which lies like a fret at the base of the walls of the overlying formation. In places, however, this conglomerate is thin or wanting and the badlands of the Chinle formation merge into the topography of the underlying Moenkopi. The red sandy shale and thin sandstones of the Moenkopi formation usually stand as corrugated cliffs under the protection of the Shinarump. The resistant and cherty Kaibab limestone forms the top of the extensive plateaus that bound the Marble Canyon of the Colorado River southwest of Lees Ferry. Within Marble Canyon, the Kaibab forms a succession of cliffs and often a sheer cliff down to the Coconino sandstone, which is in turn a persistent cliff maker. The Hermit (?) shale and Supai formation together form a series of cliffs and talus slopes down to the great cliff to the Redwall limestone which is not exposed within the area.

General Structure.—The rocks which have been described in the preceding section are affected by two structures which are of importance in the distribution of the rocks and also affect the problem of constructing a dam at Lees Ferry. The Echo monocline extends from the Painted Desert about 50 miles south of Lees Ferry through Lees Ferry and dies out to the north. Along this structure, the beds have a dip to the east of about 10° over a zone from 1 to 5 miles wide. East and west of this zone the beds lie horizontal or nearly so. In consequence of this monoclinal fold, each bed stands from 1 000 to 2 000 ft. higher in the area west of the monocline than in the area on the east. Erosion has proceeded in such a manner as to strip from the area west of the Echo monocline most of the formations down to the Kaibab limestone. The Echo Cliffs mark the zone where the folding is most intense. The second structure of importance is the general or regional northerly dip. In consequence of this structure, the Echo Cliffs and Echo monocline fade out to the north. The inclination of the beds due to this structure is from 1 to 2° and is more noticeable west of the Echo monocline than east of it. Erosion has stripped all the formations to the top of the Kaibab limestone as far north as the base of the Vermilion Cliffs. Lees Ferry lies in the angle between the Echo Cliffs and the Vermilion Cliffs. At the Ferry, the beds are dipping about 10° eastward. East of the Ferry, they are horizontal or nearly so. West of Lees Ferry at the base of Vermilion Cliffs, they dip about 1° to the north.

Character of the Rocks at the Dam Site.—Lees Ferry dam site, as recommended by Mr. La Rue, lies in the first bend of the river up stream from Lees Ferry. In Fig. 11, the distribution of the rocks is shown on a larger scale. The map is redrawn from the topographic map made by the U. S. Geological Survey in 1921. The straight reach of the river in which the dam site is to be located is carved in the massive Jurassic sandstone. The only available site for the power plant is, however, west of the ferry in an area underlain by the Chinle formation. The Echo monocline crosses the area at about the center line of the first loop of the river. West of the lines showing the Echo monocline fracture system in Fig. 11, the rocks dip about 10° to the east. East of these lines they appear to be horizontal or nearly so. Construction, therefore, as far as

FIG. 10.—VIEW DOWN MARBLE CANYON, FROM NEAR LEES FERRY, SHOWING THE VERMILION CLIFFS AND TOPOGRAPHIC EXPRESSION OF FORMATIONS DISCUSSED IN TEXT.

the dam itself is concerned, has to deal only with the massive Jurassic sandstone. This sandstone is unusually massive, having few joints and relatively few bedding planes. Almost all the sand grains are of quartz, imperfectly rounded, but without sharp edges. According to Gregory,* the Navajo sandstone or upper member of the Jurassic sandstone as here treated, consists of sand grains of two sizes. Grains of 0.15 to 0.25 mm. make up 90% of the rock, other grains, averaging 0.65 mm. in diameter, form an interrupted coat on the cross-bedding laminæ. The sandstone is somewhat loosely cemented with calcium carbonate. In addition to the lime cement, the sandstone con-

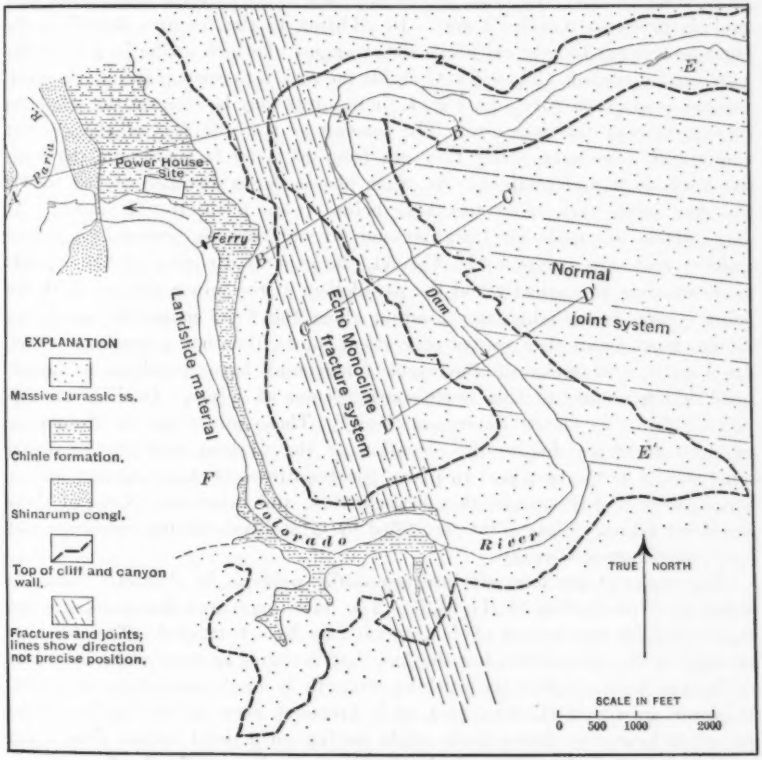

FIG. 11.

tains iron oxides which give it a red or buff color and in places, especially near the top of the formation, these oxides are concentrated in nodules or concretions about the size of peas. In places in the Navajo country, the cement is silicious. At intervals through the sandstone are beds of limestone from 6 to 18 in. in thickness, and these beds fade out laterally in short distances. The

* "Geology of the Navajo Country", U. S. Geological Survey, *Professional Paper 93*, 1917, p. 58.

limestone is gray and crystalline and, as far as known, unfossiliferous. The most striking characteristic of the massive sandstone is its cross-bedded character. The cross-laminæ are from $\frac{1}{8}$ to $\frac{1}{2}$ in. thick and consist of sand grains of two sizes, the finer grains which make up the bulk of each lamina being separated from the next lamina by a layer of larger grains. These cross-laminations extend across the face of the rock in groups of great curved lines that are generally tangent to the curve of lower groups or to the bedding planes. The cross-lamination is on a grand scale, sweeping curves being from 10 to 200 ft., or more, in length. The sandstone in places has a tendency to split parallel to these cross-laminæ. In other places, the rock is so uniform in strength that erosion produces rounded forms. In addition to the features described, the sandstone is cut by vertical joints the strongest of which strike in a generally northwest direction. These joints divide the rock into great plates along which erosion is most effective. In Fig. 4, these joints may be seen on the left hand or east side of the dam site. The spacing of the joints is of the greatest importance. In some places they are from 20 to 50 ft. apart and the walls are very sheer and straight. At other places, for a distance of 100 to 200 ft., the joints are close together, being from 1 to 10 ft. apart. At these places the walls are irregular and are cut back by narrow, steep-sided gulches and side canyons. In Fig. 11, the general direction of these joints is shown diagrammatically and the parallelism of the minor canyons with the joint system is brought out. Folding along the Echo monocline impressed on the rocks is another system of vertical joints, that has a northerly trend. In Fig. 4, the rocks of the right foreground have a schistose appearance which is due to this north-south system of joints. In Fig. 11, this belt of joints is shown diagrammatically. These joints are in the nature of fault fractures due to the elevation of the western part of the region with respect to the eastern. In places the fractures are close together and in other places widely spaced; they branch, fork, and interlace. Some of them are small faults. These joints are filled by crystalline calcium carbonate and iron and manganese oxides.

The rocks of the dam site are essentially uniform in character from the water level to the top of the cliffs. The advantages and disadvantages are thus equal for any height of dam which may be constructed. The crushing strength of the rock is low, but the fact that it stands in great walls in a state of Nature indicates that its crushing strength is ample for a high structure. However, in a rock-fill dam, such as is proposed, some of the blocks will be forced to bear very heavy loads while resting on a point rather than a flat surface. Such rocks will undoubtedly be crushed, and Mr. La Rue is correct in assuming that there will be a large amount of adjustment to load in a rock-fill dam composed of this material. This crushing and adjustment, however, will tend to compact the structure. When such adjustment is taking place, streams of water will doubtless carry away the fine débris and tend to prevent the closing of cavities.

According to Mr. La Rue's proposition, it is expected to blast down the material from the cliffs to form the dam. The rock, however, is so unusual a type that a number of problems will arise in this connection. The writer

with the assistance of Mr. Frank Mitchell made one test shot. A small amount of blasting was also done in the installation of a cable for stream gauging. This limited experience indicates that the massive but porous sandstone presents special problems in blasting. The quantity of powder necessary and the best type of holes or galleries for loading this powder will have to be determined experimentally. It should also be pointed out that the east side of the dam site is affected by vertical joints which strike diagonally to the cliff face. These joints will have a large but unpredictable effect on the blasting. The west face of the dam site from the center line south is similar to the east side, but from the center line north the rock is affected by the north-south system of joints referred to previously. The blasting in this locality may be no more difficult than in other places, but the action will be somewhat different and probably the chunks obtained will be smaller. It seems necessary, therefore, to recommend that preliminary work be done on a rather large scale to determine what the exact conditions of blasting will be, before the first great blast by which Mr. La Rue proposes to raise the dam 250 ft. above river level. When these experiments are conducted it will be possible to obtain data on two important questions. One of these is the size of blocks which can be obtained by blasting and the other is the quantity of fine material which will be produced. It seems obvious that it will be necessary to have very large blocks on the down-stream side of this proposed dam during the period when it is not yet water-tight. An unknown quantity of fine material will be produced during blasting and by the fall of blocks. In Nature, very large blocks can fall the full distance from the top of the cliffs to the bottom without breaking, but the fact that such blocks are found does not indicate how many similar blocks have been crushed by this same fall.

Location of Tunnels.—Dependent on the detailed plans which may be adopted, tunnels may need to be driven in the line of *E E'* and *A A'*, as shown in Fig. 11. Tunnels along the line, *E E'*, either for diversion of the river during construction or as a permanent wasteway after construction will be driven through the massive Jurassic sandstone entirely. Large tunnels can be constructed at a minimum of expense because of the ease of drilling the rock and because its massive character will require no support for the roof. However, unless the velocities in the tunnel are low, a concrete lining will be necessary to prevent wear. It seems likely also that there will be losses to the adjacent porous sandstone if the water in the tunnel is under great pressure and that this water percolating through the sandstone may eventually find or work out channels large enough to produce serious losses from the tunnel and direct the water toward inconvenient places. At Locality *A A'*, a tunnel may be required at a low elevation or at a high elevation to act as a spillway. A tunnel or tunnels to carry water to the power-house will certainly be built here because the flat, east of the present ferry, is the best if not the only available power-house site. The geologic section, Fig. 12, shows the character of rock which will be encountered in tunnels at various elevations. The folding along the monocline brings up the lower formations to river level and above on the west flank of the ridge. Tunnels at low elevations will pass from the massive Jurassic sandstone on the east into the red sandstones and shales of the upper part of

the Chinle formation and thence into the cherty limestone and soft shales of the middle of this formation. Tunnel construction in the middle of the Chinle formation will require thorough support for the roof and a permanent concrete lining. The red sandstones and shale of the upper part of the formation will probably present no difficulties during construction, but a lining will be required as in the Jurassic sandstone. The location of tunnels at the lower elevation becomes then an engineering problem as to relative cost of a short tunnel at Locality *A A'* or a longer tunnel at Locality *E E.'* Tunnels at Locality *A A'* and at an elevation of 650 ft. will be required for carrying water to the power plant. These tunnels will be wholly within the Jurassic sandstone and require no comment either on their construction or location.

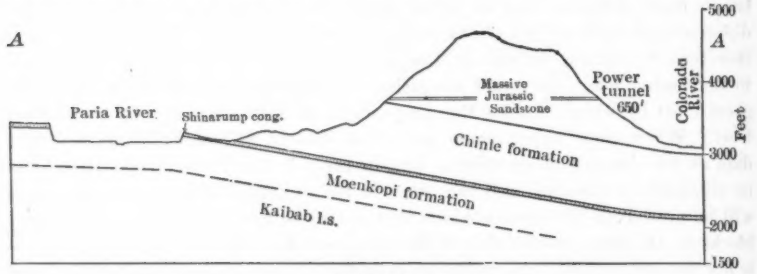

FIG. 12.

Leakage.—On the assumption that the water-tight dam to an elevation of 720 ft. is constructed in the straight stretch of river east of Lees Ferry, consideration was given to the problem of leakage. The west wall of the reservoir is relatively narrow, but the massive Jurassic sandstone is cut by numerous sealed joints, as mentioned previously. It is considered that these joints will form fairly perfect obstacles to percolation. Similarly, the folding which has carried the Chinle formation up to elevations of about 3 500 ft. on the west side of the ridge near the present ferry has laid a dam of rather tight rocks in the path of percolating waters. On the east side of the dam the reservoir wall is formed by the massive Jurassic sandstone. The minimum distance through this wall is about 6 000 ft. A certain amount of direct percolation through the pores of the rock may be expected, but most of the leakage will occur along vertical joints. However, the direction of these joints, as shown on Fig. 11, is nearly at right angles to the direction of this flow. If considerable leakage should take place through the sandstone and large springs break out below the toe of the dam and in the canyon at Locality *E'*, it seems unlikely that such leaks would affect the stability of the canyon wall.

Depth of the River Channel.—During mean high water the depth at the gauging station above Lees Ferry ranges from 13 to 17 ft. The bed of the river is composed largely of sand. Near the margin of the channel are numerous large rocks which have fallen from the cliffs. Many of these seem to be relatively stable in position and not easily dislodged by floods.

It is practically impossible to predict the distance to bed-rock in such a channel. If the river has cut its bed normally, the thickness of gravel and

sand will be only that of scour and fill during great floods. Such scour and fill should be relatively moderate in amount, but is an unpredictable quantity. The Shinarump conglomerate crosses the river channel west of the ferry (see Fig. 11). Mr. La Rue believes that bed-rock extends across the channel at this point at low water. If this ledge exists, then there has been no general silting of the channel. At the dam site there may be, however, a hole or deep in the rock bed of the river due to the presence of a fossil plunge-pool. A plunge-pool or over-deepening of the stream bed occurs at all falls and it seems possible, although there is no direct evidence, that the Glen Canyon of Colorado River was cut back as a head-water falls from the line of Echo Cliffs eastward. As the falls receded, successive plunge-pools would be filled with gravel to bring the river to a uniform grade. It seems necessary for the determination of the depth to bed-rock to proceed in the usual manner by drilling.

Observations on the Scheme for a Rock-Fill Dam.—Mr. La Rue's scheme for a rock-fill dam, which is to be made water-tight by sluicing in a fine material during construction, is a bold solution of the problem for a dam at Lees Ferry. The difficulty of obtaining suitable material as well as the isolation of the locality required such a solution, and the author is to be complimented on his originality and vision. In advance of building such a dam it may be assumed that the thickness and character of the sand and gravel above bed-rock will have been determined and that experiments will have been conducted to determine the best method of blasting the massive sandstone walls.

According to Mr. La Rue, fine material for filling the interstices of the dam can be found up stream at various sand-bars and banks. A roadway up the canyon is impracticable and the navigation of the canyon is attended with some difficulties, even with the assumption that preliminary blasting will raise the water level and pond the water for a distance of 15 or 20 miles. Therefore, another source of fine material was sought. The Moenkopi formation consists largely of sandy shale and might make suitable material for filling such a dam except for its rather high content of gypsum and other soluble salts. Continual solution of this material would make it an ineffective filler for small spaces. Similarly, the base of the Chinle formation, consisting of gray, green, and blue shales, is suitable in that it is clayey, particularly where it is weathered, but this formation also contains a considerable quantity of soluble material. Systematic sampling and some simple laboratory work might show that these clays could be used. The upper part of the Chinle formation consists of heavy, bedded, earthy sandstone and sandy shales, and this part of the formation appears to be rather free from salts, but it is so exposed in cliffs that it can not be easily quarried. It occurred to the writer, therefore, that the heterogeneous landslide material on the south bank of Colorado River opposite the ferry, in the general locality marked *F* in Fig. 11, might be a suitable source for part of this material. The material has been in position for some time and the soluble matter has doubtless been leached out. There is also a large sand dune which is free of soluble matter. By installing a crusher and mixer, the surface of this slump or landslide area and the dune could be stripped with steam shovels and crushed, obtaining as a result a mixture of disintegrated

shale and leached sandstone which would have a texture similar to loam. Loaded into cars, this material could be brought across the river and carried to the top of the bluff on an inclined railway. The use of this material depends on its relative cost.

It seems probable that in blasting the cliffs a large quantity of fine material would be obtained and, unless precautions are taken, it is likely to be lost. If as a preliminary to the large blast, which is to raise the dam to 250 ft., a small low dam is thrown across the river at or slightly below the toe, the dam would then be built in slack water and much more fine material would be saved.

Mr. La Rue's scheme is generalized, and he has assumed that blasting in the cliffs would produce a relatively even crest line at any given point on the dam, but it should be borne in mind that the material will slide into the dam site in the manner of a series of talus cones and the low point of the dam at any cross-section will be near the center line of the river. The difficulties may be visualized by a consideration of the cross-sections shown in Fig. 13. Line *C C'* is at the center of the dam as proposed by Mr. La Rue, and the other lines at the upper and lower points, respectively. In Cross-section *C C'*, a 1 on 2 slope has been projected. It is possible that when blasted the material will slide into the lower part of the canyon on this slope, but it is unlikely that the heap of loose material will stand on this slope. It seems more likely that it will assume a slope between 35 and 50 degrees. The existing talus which occurs at intervals along the canyon walls doubtless has the minimum slope. Three talus cones shown on the large topographic map of the dam site have maximum slopes between 29° 30′ and 33° 30′. The artificial cones will be less stable and will probably have coarser material. Overtopping of the dam during construction is a serious matter if the water will be concentrated in a V-shaped trough near the center line of the dam, because the maximum velocities will thereby be obtained. It may be necessary, therefore, to hand-place a considerable part of the material near the longitudinal center line of the dam, or to blast in an excess of material so that the center line will be the required height.

Materials for Construction.—The local materials available for general construction purposes are considered in the following paragraphs.

The Coconino sandstone, Hermit (?) shale, and Supai formation are exposed only in the Marble Canyon or its tributary canyons. The outcrops are so inaccessible that these formations may be dismissed as sources of material.

The Kaibab limestone is exposed over large areas southwest of Lees Ferry, and there are numerous places where quarrying can be done economically. The formation is about 250 ft. thick and consists almost exclusively of yellow limestone with nodules of chert. No beds were seen which gave any promise of being valuable for making cement. Dimension stone of large or small size can be readily obtained. The hard chert nodules are so numerous that the cost of facing blocks with a chisel or hammer will be large. The rock can be considered as available only for rough ashlar or rubble masonry. It would, however, make excellent crushed rock for concrete or macadam.

The Moenkopi formation is a sandy shale with interbedded thin sandstones and contains considerable gypsum. It is valueless for structural purposes.

The Shinarump conglomerate is about 40 ft. thick and forms a gray ledge above the "dug way" and the ridge on the east side of Paria Creek. It is a cross-bedded conglomerate of well-rounded silicious pebbles with lenses of sandstone and small lenses of green shale. Fragments of fossil wood and logs of trees are abundant. This conglomerate is hard and durable, has widely

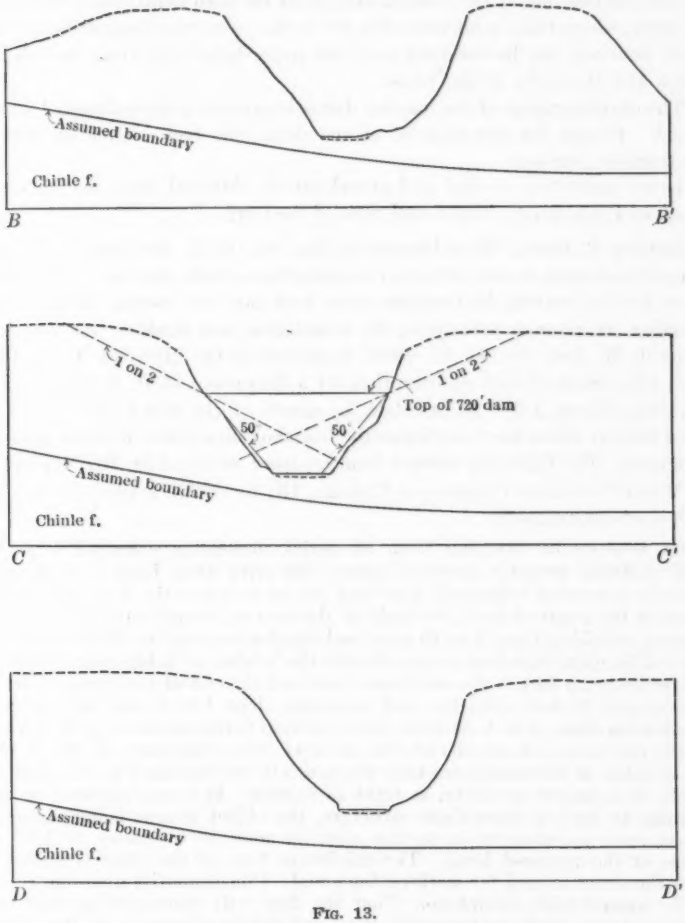

FIG. 13.

spaced vertical joints, and is an excellent rock for rubble or Cyclopean masonry. It is somewhat too hard and coarse-grained to be easily worked into blocks of uniform dimension.

The Chinle formation is a very complex unit consisting of gray, green, and blue shale below, white and purplish sandstone and shales, cherty limestone and

shales in the middle part, and in the upper part massive red sandstones and shales. Only the upper part contains material of any value for construction purposes. The red sandstones have a pleasing color, can be obtained in large and small sizes, and are easily worked. They have no great crushing strength, nor are they suitable for masonry which is to be alternately wet and dry. The best site for a quarry from which to obtain these sandstones that might be used for the construction of the power-house, is on the high point south of the present ferry, where these sandstones dip 10° to the east. Small quantities of such stone, however, can be obtained near the power-house site from the adjacent ledges and the rocks of the talus.

The characteristics of the massive Jurassic sandstone have already been discussed. Except for the rock-fill of the dam, this rock is not suitable for construction purposes.

Large quantities of sand and gravel can be obtained from the bar at the mouth of Paria River about a mile west of the ferry.

ARTHUR P. DAVIS,* PAST-PRESIDENT, AM. SOC. C. E. (by letter).—The first proposition known to the writer for constructing a high dam in a large stream on an alluvial bottom, by dumping loose rock into the flowing water without diverting the river or excavating the foundation, was made by the late A. G. Menocal, M. Am. Soc. C. E., Chief Engineer of the Maritime Canal Company, who proposed such an operation for a dam about 65 ft. in height on the San Juan River, a few miles below the mouth of the San Carlos at a point called Ochoa, where the river forms the boundary line between Costa Rica and Nicaragua. The following extract from a paper† prepared by Mr. Menocal for the Water Commerce Congress at Chicago, Ill., in 1893, describes the dam and method of construction:

"It consists in dumping from an aerial suspension conveyor large and small material properly assorted, across the river from bank to bank until a barrier is created sufficiently high and strong to arrest the flow and hold the waters at the required level, the body of the dam to be made up of large blocks of stone, weighing from 1 to 10 tons, and smaller material to fill the voids. Its base will be quite broad as compared with the height, probably from 400 to 500 feet between the foot of the upstream slope and the end of the apron. The top is estimated 30 feet wide, the rock upstream slope 1 to 1, and the apron, or downstream slope, 4 to 1, with the lower portion flattening down to 5 or 6 to 1. On the upstream side small material, such as stone, fragments of gravel, clay, etc., selected as circumstances may require, will be deposited as the work advances, in sufficient quantity, as tight as wanted. It is not expected or even desirable to have a water-tight structure, the object sought being simply to oppose such an obstruction to the river as may be necessary to hold the waters at the required level. The minimum flow of the river is about ten times the water needed for working the canal. Consequently, nine-tenths of it can be wasted with advantage. That the dam will eventually become tight there can be no doubt, as the small drifts and detritus forced in by the current will gradually fill the voids and consolidate the structure.

"The method of construction will be quite simple. After protecting the abutments against possible erosion, large pieces of rock will be dumped in the bed of the stream from three or four cableways spanning the valley. The

* Director, U. S. Reclamation Service, Washington, D. C.

† H. R. Document No. 279, 54th Cong., 1st Session, p. 53.

material should be distributed uniformly over the area under the main portion of the dam, commencing up stream and keeping up, as nearly as possible, an even level. Scouring will soon cause settling of the blocks into firmer soil, the upper level in the meantime being constantly raised by depositing more stone, while the small material is being forced by the current into the voids, and the overflow dislodging and rearranging the unstable blocks until they reach a final resting place. This process to be continued until the resistance at the bottom becomes so great as to check scouring due to maximum pressure, when the dam will be carried up to the desired level. The river, in the meantime running over the mound, will readjust the material in and adapt the apron to the necessary conditions of stability to withstand the effect of the fall, and carry off the water safely. If the dam is then raised so as to shut off a whole or the largest part of the river flow, which can by that time be discharged over the waste weirs, the structure will be permanent."

It was proposed that this dam be an overflow weir, and this feature has been generally condemned.

The Nicaragua Canal Board, consisting of the late William Ludlow, M. Am. Soc. C. E., Mordecai T. Endicott, Past-President, Am. Soc. C. E., and the late Alfred Noble, Past-President, Am. Soc. C. E., studied the plans of the company and made the following comments* on this design:

"It appears from this account of typical existing dams that, although rock-fill dams are not new, and although weirs have been built on sand and maintained successfully, the Ochoa Dam is actually without precedent in its more serious aspects, and its construction will be far more difficult than any that have been mentioned. The successful rock-fill dams have impervious foundations, and are made water-tight by sheathing or masonry. The materials in them are in great part hand laid, adding greatly to their stability, and none of them has been built in conflict with the forces of a great river or was intended to be used as a weir for the discharge of floods.

"As to this last point, the Board is clear in its judgment that no such endeavor should be made in the case of the Ochoa Dam, as involving an unwarrantable hazard to the safety of the structure and of the canal navigation."

* * * * * * * *

"The weakest point of a dam built as the company proposes would probably be at the river bank, where the loose rock will meet the steep clay slope. The method proposed for protecting this point by lines of sheet piling and concrete core seems entirely inadequate. A better construction would involve the use of a caisson on each side of the river, located so as to be partly in the river channel and partly in the firm clay bank, and sunk by the pneumatic process to bed rock if within reach by that means, or if not at least below reach of scour. It seems probable that either bed rock or a mass of boulders would be found near sea level, elevation 0. The caisson should be surmounted by a concrete wall, extending up the hillside beyond the caisson to the highest elevation to be reached by the water surface after the completion of the dam, say 114 or 116. A trench 20 feet or so in depth, or deeper if necessary to reach firm material, should be excavated in the hillside for the core wall. This work done, the river banks and hillsides below high-water level should be covered with a heavy mass of large stones and an additional amount held in reserve before depositing any rock in the river. The result of this would be to contract somewhat the width of the river channel, which would at once scour out so as to maintain its normal cross section. A considerable scour would be desirable, because it is important that the rock mass be sunk deeply

* H. R. Document No. 279, 54th Cong., 1st Session, pp. 61–64.

into the river bed, since, if rock or a bed of boulders or heavy gravel can be reached, the safety of the structure will be increased greatly. In depositing rock in the river those methods should be used which will induce scour, and possibly the building out from each side may best answer this purpose."

* * * * * * * *

"The rock mound would be quite permeable, and the water pressure against it would vary with the volume of the discharge. To make it hold water, an embankment, which would form the real dam, the rock mound serving as its support, must be built on the upstream side. It is proposed to make the embankment of fine stone, gravel, clay, etc., with the view that a quantity of these materials should be carried well into the rock mound. An embankment composed largely of clay dumped in the water would take a much flatter slope than 3 : 1. For these reasons the quantity estimated by the company would have to be increased largely, and means may have to be adopted, not contemplated by the company, to render the dam tight enough to answer its purpose, as the permissible leakage is much less than the company has assumed.

"By the addition of the embankment, and the retardation by friction of the flow of water through the underlying sand bed, the dam will be rendered more secure from undercutting and consequent settlement; but some doubt as to ultimate security will still remain. Confidence would be gained to a certain extent during the construction of the dam, if no breaches were caused by the annual floods, but it would require a considerable period of time after the completion of the dam to allay all apprehension. If a site can be found where the dam can be built above a rock or other stable foundation, the permanence of the structure will be rendered much more probable and the uncertainties of construction reduced.

"If such a dam becomes breached with the great volume of water standing at a high level against it, destruction would follow quickly. The crest, therefore, should be raised so far above the surface of the water in the pool that a considerable settlement could be sustained without sinking the crest below the water surface."

It should be noted that the Board places emphasis on the importance of scour in settling the foundation as far into the sand as possible. It is also to be noted that this eminent board of engineers was doubtful of the permanent safety of a dam even of this height under these conditions.

The practical application of the method of damming a large river by dumping rock on a bed of silt while the river flowed over it was made by the Southern Pacific Company in 1906, in the spectacular control of the Colorado River when it was flowing into Salton Basin. The same method was used in constructing a coffer-dam across the Colorado River in making the final closure for the Laguna Dam. In neither case, however, was the water allowed to flow permanently over the rock-fill, as proposed by Mr. Menocal, and the rock used was settled deep into the silt by the erosion of the water during construction.

The author proposes no means for effecting a water-tight junction between the rock-fill and its abutments, and the writer sees no effective method of accomplishing such a junction between the proposed silt filling and the rock. Under such a head, water would follow the rock with a velocity likely to become erosive at many points, and thus open avenues of danger. The best solution seems to be a concrete pavement cemented to the abutments with all the

care and precaution that the highest skill can suggest. Cracks which might appear should be sealed with a cement gun at the first opportunity.

In considering the construction of a loose rock dam in Boulder Canyon during the past few years, the Government engineers and those whom they have consulted have regarded the settlement of the loose rock into the soft material as deeply as possible as one of the most important and difficult operations to accomplish, and it seems obvious that it cannot be made perfect without excavating the loose material, but might perhaps with many precautions be made to sufficient extent to secure safety.

The author's proposal to deposit enough rock in the river at one blast to bring the dam to the 250-ft. level seems especially designed to prevent any water action in the direction of scour and of sinking the rock into the silt. He says:

"If the canyon walls were blasted into the river, the heavy mass of material would settle to the level of the boulders, assumed to be 60 ft. below the bed of the river, and some of the fine sand and silt would be forced up."

No reason is given for this important conclusion and the methods proposed seem likely to prevent this desirable result.

If this dam was built by the methods suggested by the author, there would be a considerable part of the structure below the river bed founded on sand and silt. As the water rose in the reservoir after the dam was completed, the head on this silt would gradually increase and no assurance could be given that a critical point might not be reached when the reservoir is nearly full, and sufficient percolation through the foundation might take place to start erosion and cut a channel through the silt. A free passage ever so small, resulting from the slight arching of the rock, that would conduct water through the sand at a velocity due to more than 700 ft. of head, would scour rapidly, carrying considerable rock, until a channel was excavated large enough to allow the rock above to settle, and unless this was accomplished in one motion the scour would continue until the main rock-fill fell into place. If it was arched sufficiently it would not do so promptly, and the scour would continue until the opening would carry a flood much larger than normal and do great damage below. It seems inevitable, however, that eventually the rock-fill would fall in place and stop this. If, in so doing, it should fall below the level of the water in the reservoir, the dam would be overtopped. No loose rock dam has ever been overtopped without failing, and some have failed. None of them has had a 780-ft. head nor 50 000 000 acre-ft. of stored water behind it to complete its destruction.

It should be remembered that the proposed reservoir of 50 000 000 acre-ft. has an area of 235 000 acres, and a discharge of 1 000 000 acre-ft. would lower the reservoir only about 6 ft. This would afford an average flow of 500 000 sec-ft. for 24 hours. No one can doubt that this would destroy the dam faster than it would lower the reservoir. The writer will not attempt to describe the results of suddenly releasing 50 000 000 acre-ft. of water. It would at least submerge and destroy the great Imperial Valley and all improvements along the Lower Colorado River, and doubtless many lives would be lost.

It is readily seen that both the danger of failure and the magnitude of the disaster are greatly augmented with the height of the dam. This law applies especially to an unprecedented or doubtful design.

Where the necessary structure so far exceeds precedent, to build it any higher than needed would be inexcusable. The author appears to consider a capacity of 20 000 000 acre-ft. to be sufficient to regulate the river. The writer agrees with this estimate, but would provide 20% more to store silt and prolong the usefulness of the reservoir. There can be no reason therefore for building a reservoir of greater capacity than about 24 000 000 acre-ft., except for the increased head for power development. This site is so remote from markets and so much farther than many other available sites that there is at present no excuse, and for many years or decades there will be no justification, for developing power at this point. The available head can be utilized by building dams of moderate dimensions at other points without such unprecedented and hazardous characteristics.

The author states that the construction of a dam near Lees Ferry would remove the menace from floods on the lower river, except floods from the Gila River. That statement is erroneous, as the proposed dam would leave about 50 000 sq. miles of drainage area unregulated, besides that of the Gila. It is perfectly proper, as the author does, to except the Gila River, which for brief periods sometimes furnishes floods as great as those of the Colorado; but the area of 50 000 sq. miles between the mouth of the Gila and Lees Ferry should also be excepted. Most of this area can be intercepted by a dam at Boulder Canyon, which is the lowest point in the basin where this can be done, and is accordingly the proper place for storage purposes if the floods are to be controlled.

Table 1 shows a capacity for Lees Ferry Dam of 50 000 000 acre-ft. and for Boulder Canyon Dam of 31 680 000 acre-ft. The results of the actual surveys were probably not available to the author when he submitted his paper. These surveys have been in progress for a long time, and the results are now available and are shown roughly in Table 3 which gives the comparative area and capacity for each given height of the dam, as high as the surveys have been carried at Boulder Canyon.

Table 3 shows that, for the heights given, the Glen Canyon Reservoir would have less capacity than Boulder Canyon.

A dam 780 ft. in height in Glen Canyon near Lees Ferry would introduce not only unnecessary hazards, but would waste a large quantity of water by evaporation. A reservoir of 24 000 000 acre-ft. capacity in Glen Canyon, would have an area of about 125 000 acres, according to the available surveys, whereas one of 50 000 000 acre-ft. capacity would have a surface area of 235 000 acres and unnecessarily expose to evaporation 110 000 acres. This would be at its highest stages during the hot months of June, July, August, and September. Assuming an average excess area of 100 000 acres, and an annual evaporation of 6 ft. from the extra area, 600 000 acre-ft. of water would be wasted annually, all of which would be lost for use at the numerous high dams eventually to be built in the canyon below.

The absence of a precedent to the proposed plans leaves the writer in doubts much the same as those which remained in the minds of the members of the Nicaragua Canal Board previously quoted, and there apparently is sufficient doubt so that it would be inexcusable to attempt such a structure

TABLE 3.

Height of dam above river bed, in feet.	Boulder Canyon Reservoir.		Glen Canyon Reservoir.	
	Area, in acres.	Capacity, in acre-feet.	Area, in acres.	Capacity, in acre-feet.

where more conservative designs are possible or to build the dam under these conditions any higher than necessary.

Opinions concerning the safety of the proposed design can hardly be considered of much value until something is known of the underground conditions, which have not been investigated at Glen Canyon. Still less is it possible, under these conditions, to make intelligent estimates of cost of any type of dam. These conditions at Boulder Canyon have been carefully investigated, and comparative estimates of high concrete and rock-fill dams have been made by men with wide experience in the construction of high dams. These estimates lead to the conclusion that the rock-fill type, with proper precautions for safety, could not be relied on to be much cheaper than a massive concrete structure the safety of which would be without question.

J. C. Stevens,* M. Am. Soc. C. E. (by letter).—Mr. La Rue's plan of constructing in the Colorado River a rock-fill dam 780 ft. high and a base width of more than a mile is novel and bold. He has stated the reasons the plan should not be adopted, when he says, "this mass of loose rock would not be water-tight, which feature is the most uncertain in the plan here presented."

The writer believes, however, that his plan might well be given further investigation with a view to modifying the design and method of construction so as to remove this uncertainty.

There can be little doubt that a rock-fill dam to the height proposed will stand throughout the ages and will not involve the uncertainty of stresses that would attend the design of a solid concrete dam to this unprecedented height. The only question is whether it can be made water-tight at an expense that will give it an advantage over a solid dam.

* Cons. Hydr. Engr. (Stevens and Koon), Portland, Ore.

The writer thinks the plan of making a dam 200 ft. high by one blast from the canyon sides is somewhat fanciful. Under the conditions assumed, namely, 100 ft. to bed-rock and a water surface width of 450 ft., and, further, assuming that the canyon sides slope $\frac{1}{2}$: 1, a fill that would raise the water 200 ft. would have a projected area of 150 000 sq. ft. The finer material would undoubtedly be washed away, leaving a fill composed of rocks from the size of cocoanuts to box cars. The voids in this mass would be at least one-third, through which the water would readily pass at a velocity of 0.5 ft. per sec. Thus, a flood of from two to five times the summer flow might pass through the fill before water reached the 200-ft. level.

It would be almost impossible to reduce this leakage to safe quantities by any amount of blanketing. For instance, for a leakage of 500 sec-ft. the velocity through the mass would be about 0.003 ft. per sec., or 250 ft. per day. Water travels faster than this in natural sand and gravel beds, moraines, etc. The first blanketing of stones, gravel, and earth would tend to fill the voids somewhat in the up-stream face of the fill, but this would reduce the velocity so that no more material would be carried into the fill. The leakage thereafter would become that through the blanket itself, and, although the velocities through it could be reduced to very low values, the aggregate amount of leakage would be great on account of the enormous area exposed to the water.

It seems to the writer that a type of dam worth consideration would be a combination of solid concrete and rock-fill. By way of a suggestion: Unwater the river by means of a tunnel and a coffer-dam at the river level. Then build a solid concrete dam to a height of 50 ft. above the river surface, and let this dam form the up-stream toe of a rock-fill to the full height of 780 ft., the rock-fill to be faced with pre-cast reinforced concrete slabs anchored together to form a flexible facing to the fill and joining with the solid concrete dam at the toe. Heavy eye-bolts should extend through the slabs in both directions, by which each could be flexibly joined to its neighbors. After placing, the joints should be filled with asphaltum.

This presupposes that the rock-fill will be placed, not dumped, and that the up-stream third of the dam will be essentially a dry wall. The slopes of the fill need not be more than 1:1 on the up-stream side and 2:1 on the down-stream side. Just how much of the rock-fill should go to bed-rock, if any, could only be determined after the character of the foundations was known.

J. H. Quinton,* M. Am. Soc. C. E. (by letter).—The author is entitled to much credit for his valuable contributions to the knowledge of the physical features of the Colorado River, not only in his paper, but also in public documents.

It cannot be said, however, that he has contributed much to the knowledge of building dams in great rivers, for he proposes a plan for building a dam in the Colorado River, in which he substitutes blind force and haphazard methods founded on "beliefs", for technical skill and knowledge founded on well-known principles.

* Cons. Engr., Los Angeles, Calif.

The author's idea of blasting the loose-rock portion of a dam in place is not new, as it was tried at both the Lower Otay and Morena Dams, but was not successful. The loose-rock portion of the Lower Otay Dam was composed of a mass of quarry refuse above the steel core, and of larger rock below that core.

The author proposes to build a dam, below which the water is allowed to percolate, by blasting rock from the cliffs on both sides of the canyon. Such a dam must be of such length, up and down stream, that the underground water emerging from its lower toe will not have sufficient force to carry away the sand or silt from the river bed or from the interstices of the material composing the dam. This length depends on the kind of material composing the river bed and, for each material, has a definite ratio to the head of water above the dam. For such material as that composing the bed of the Colorado River, this ratio is between 12 and 15. The flow of water under the dam may be treated as the flow of water in a pipe filled with sand or other permeable material.

The water is never allowed to pass lengthwise through the dam, and is prevented from doing so, either by a concrete wall, or an upper slope of impermeable material. The dam itself may be either permeable or impermeable. In the former case, the surface of the lower slope must be above the hydraulic grade line at all points. In the latter, the impermeable material below the hydraulic grade line must be heavy enough to resist the upward pressure of the water, with a reasonable factor of safety.

A good example of the former is the Laguna Dam on the Colorado, in which the ratio of length to head is 13.5, and a good example of the latter is the Granite Reef Dam on the Salt River Project, built by the U. S. Reclamation Service. The Laguna Dam, however, was not built by blasting a mass of rock into the river bed, but, like all dams which have stood the test of floods, the rock was laid in place with care. Three concrete cross-walls, each 5 ft. thick, and extending across the river bed, from bed-rock on one side to bed-rock on the other, serve to hold the loose rock in place. The top layer of rock was laid to an even slope by hand and set in cement concrete. This is a diversion dam, and is only 19 ft. high, from the bed of the river to the top of the concrete wall at the crest. The dam proposed by the author, if properly designed, would have to be at least 13.5×780, or 10 530 ft. long, up and down stream, would have a volume of about 106 000 000 cu. yd., and require the blasting of at least 50 000 000 cu. yd. of rock. This material, if laid carefully on the bed of the river to form a stable dam, would probably cost $1 per cu. yd., or more.

If the rock is blasted in great masses into the canyon and the river allowed to "work its sweet will" on it during the flood season, a great deal of it would be carried down stream. Much of it would also sink into the sandy bed of the river, and in a year or two probably another 50 000 000 cu. yd. of rock would be required. As designed by the author, the dam would not withstand 650 ft. of water even if all the material composing it were laid carefully in place, for the reason that the water would fill the interstices of the material. The mass would become fluid and would not stand on a slope of 4:1 or 6:1.

It would creep gradually down stream, and as soon as the water of the reservoir commenced to pass over the top, it would be destroyed.

Some of the rock-fill storage dams which have stood the test of full reservoir and great storms are the Minidoka Dam (90 ft.), built in 1904, by the U. S. Reclamation Service, in Snake River, the Zuni Dam on the Zuni Indian Reservation, New Mexico (70 ft.), and the Morena Dam of the San Diego (Calif.), Water-Works (160 ft.).

Each of these dams has an impermeable or slightly permeable "curtain" or "cut-off", carefully connected to an impermeable and stable foundation. The loose-rock pile in a storage dam is not only a support, but also a blind drain for the slightly permeable material, and is generally of such dimensions as to withstand, alone, the pressure of the water, with a reasonable factor of safety against rupture or sliding. There is no record of a storage dam of the rock-fill type having been constructed without an impermeable cut-off connected to an impermeable foundation.

In this type of rock-fill, it is considered unsafe for the loose-rock part of the dam to rest on any but an impermeable foundation, as there may be considerable leakage due to imperfect work or material, in addition to the natural leakage which is to be expected through the material of the curtain. If this leakage should be sufficient to saturate the material under the loose-rock pile, settlement of the rock will occur, which would affect the stability of the dam, and eventually cause its destruction. It will be seen that to build a properly designed rock-fill dam in the Colorado River, it would be necessary to make an excavation large enough to support the rock pile on bed-rock, or other impermeable material, such as cemented gravel. The excavation alone would cost more than a masonry or concrete dam complete, and this plan, therefore, may be dismissed as impracticable.

Nothing has been said of the advisability of building a rock-fill dam 780 ft. high, even if it were practicable. A dam of such unprecedented dimensions, and in such a great river as the Colorado, would have to be of masonry and as solid as the rock cliffs above it, in order to be safe and to inspire confidence in the people living below it. The dam proposed by the author, and his method of building it, is nothing more than a dream, or a vain imagining. "The baseless fabric of this vision" is the proposition, first to blast in place a dam 250 ft. high, with a gradual lower slope extending nearly a mile down stream. Nothing is said about the upper slope of this dam, which may be supposed to adjust itself to the angle of repose for material of this nature. Even if this could be accomplished, the water would not rise to the 200-ft. level, because it would flow freely through the interstices of the rock which forms about 50% of the mass (instead of 15% as stated by the author), and would cease to rise when that flow equalled the flow of the river above the reservoir.

The writer feels that he has said enough to show that the dam proposed by the author is not practicable. Great engineering structures cannot be founded on "beliefs" unless there are "cold facts" to justify them, and none of the latter is found in this paper. It seems unfortunate that so many people,

even those in high places, should have expressed their belief that a loose-rock dam could be built by blasting cliffs into a canyon of the Colorado River, and it is hoped that this discussion will put an end to this foolish idea. Such ideas expressed by engineers, when not backed up by facts and knowledge, only cause ridicule among those who have had experience in building dams in great rivers, and give the general public a wrong impression which is sometimes difficult to eradicate.

ERNEST H. BALDWIN,* M. AM. SOC. C. E. (by letter.)—The magnitude of the proposition for damming the Colorado River, advanced in such an interesting manner by the author, would be sufficient in itself to attract the attention of engineers interested in this branch of engineering, but this feature, combined with many other data relative to this important but perplexing river, makes this paper extremely valuable.

The general proposition of a high dam on the Colorado River, whether at Lees Ferry or Boulder Canyon, is undoubtedly feasible and of prime necessity, but in constructing such a dam there should be no guesswork, no radical departure from the tried and tested methods that have proved successful and that require only expansion, and most careful planning, to insure their success in the Lees Ferry Dam.

The writer has had experience in the blasting of rock into rivers for the purpose of forming rock-fill dams, although on a scale small in comparison with the dam proposed by the author. The most carefully laid plans will miscarry in this method of building dams, and where millions of cubic yards of rock are to be placed without interfering with irrigation, a miscalculation may be more expensive than another type of dam.

It is stated that, at the site of the Lees Ferry Dam, the bed-rock is probably overlaid with 40 ft. of boulders and sand and 60 ft. of fine sand and silt. This means that several million cubic yards of the first rock blasted would settle down, as the upper 60 ft. of sand and silt was eroded, until it rested on the bed of boulders. As the head of water increased, there would be considerable scour, with consequent leakage.

Mr. La Rue states that the first shots will blow enough rock into the river to form a dam 250 ft. high, and extending to the toe, more than a mile down stream. With the settlement due to erosion, this means about 20 000 000 cu. yd. of rock, and the blast would require about 500 tons of explosives to bring the dam to the dimensions mentioned. This is an enormous quantity of rock, too much to have misplaced.

If such a blast was feasible, the rock would pile up 100 or 150 ft. from each shore, much of it fine material, but more of it in masses of 100 to 1 000 tons, depending on the placing of the mines and the manner of loading. It would not be well mixed, the fine and the coarse rock settling at different distances from the shore. The central 100 ft. or more of the river would form a channel that would scour to the boulder formation at least, and the large masses of rock would arch, forming immense caverns that could never be filled. The material for the central, or channel, part of the dam would

* Springfield, Mo.

have to be placed by another method, and the swift current would probably transport most of that material beyond the toe.

To build a rock-fill dam as suggested by the author, would mean an extensive plant for handling and placing the material, as not more than one-third of it could be blasted into place and that could not be made tight by feasible methods. The writer believes the plant required to complete the dam would be almost as elaborate and expensive as one required to build a concrete structure.

The author suggests that 10 000 000 cu. yd. of fine rock, sand, and silt might be required to tighten the dam. This, in itself, would require a large plant for loading, transporting, and placing. To be effective, the tightening material would have to be deposited in such a manner that the reservoir water would carry it at least to the center of dam, which would mean a long, tedious, and expensive process.

Should it be found, after the initial blast of about 20 000 000 cu. yd. of rock, that conditions were as previously suggested, then several million dollars would have been wasted and a good dam site spoiled.

In the writer's judgment, a dam 780 ft. high could be more economically constructed of concrete if the foundation was found to be suitable. The natural conditions at and adjoining the site seem to be favorable for the making of aggregate and the placing of concrete.

C. S. Jarvis,* M. Am. Soc. C. E. (by letter).—The proposed plan for a 780-ft. rock-fill dam on the Colorado River is startling in many of its details, but the character and achievements of the author are such as to command a more serious consideration than would be accorded otherwise.

The remoteness of the proposed site from industrial centers might be urged against the project; but the idea of such a type of construction should be examined on its merits, for there are many dam sites more favorably located, with the same characteristics, but generally of smaller dimensions, than the one described at Lees Ferry. The question is mainly as to the practicability of such a dam, as the author specifically states in his introductory remarks.

The transporting power of running water is fairly calculable; but formulas do not take into account the action around the larger boulders. These may appear in the bed of the stream, partly submerged in rock waste or silt, and, when the flood is at its height, erosion will occur around such an obstruction. When a sufficient space has been cleared laterally and down stream, the boulder may slide or roll a short distance, and the alternate scouring and movement will be repeated. During the receding stage of the flood, the hollows down stream from the boulders are generally filled in part, so that an observer might consider such large stones safe against movement, if he neglects the effect of erosion, as described. This relentless scouring adjacent to obstructions is the element most directly opposed to the type of high rock-fill dam under discussion.

There is no doubt that, with suitable preparation and blasting, large enough masses of rock could be dislodged to create a loose rock-fill; but, to the writer,

* Civ. and Cons. Engr., Salt Lake City, Utah.

it appears improbable that a mud bank would form up stream and "make the rock-fill water-tight to an elevation of 50 to 100 ft. above the bed of the river"; that such a bank could be raised ahead of the rising water surface of the reservoir so formed; or that the rock-fill could be made reasonably water-tight in the midst of such a river, if such a mud bank should be formed and then overtopped at a height of 100 ft. If 20 000 000 cu. yd. of rock were thrown into the river gorge, as outlined by the author, the rapids formed thereby would exert their power to remove the obstruction, eroding at the down-stream toe, and rolling or sliding the protruding boulders into the hollows thus formed, until the rock-fill had spread, settled, and displaced sufficient of the river sand and gravel to insure stability for that particular stage of flow. A higher flood stage would probably cause a resumption of the process of erosion and shifting. During the low-water stage, the entire flow of the river might run through the rock-fill, and the erosion and transportation of the finer materials would continue, mainly from the up-stream section of the dam.

The writer served as engineer on one irrigation project where time limits and flood conditions required the placing of a 20-ft., concrete, diversion dam partly on bed-rock and partly on a rock-fill in the midst of a rapids in the river channel. It was well known that leakage would result, with no danger to the structure. A rock and earth-fill dam was to adjoin the concrete section and extend to the opposite bank on and immediately up stream from the rock-fill in the river bed. The structures were built during flood stages of the stream, and maintained safely; but to stop the recurrent and persistent leaks through this rock-fill required the placing of an additional volume of finer materials about equal to the volume of the structure as originally planned; and, finally, during a low stage of the river, a cut-off wall was placed through a part of the river bed, at the up-stream limit of the dam, to prevent the recurrence of leaks and slow erosion of the finer materials.

The construction of several rock-fill dams with puddle cores on glacial drift, together with observations on these structures in service, and the lateral and terminal moraines which serve as the retaining embankments for reservoirs and lakes of great depth, have convinced the writer that a combination of rock-fill and hydraulic-fill may be built and maintained safely at such a height as the author has suggested; but a pre-requisite for making it reasonably water-tight and dependable would be the positive checking of the underflow and the control of the river during construction, to prevent the segregation and loss of the finer materials.

Those who have had to construct measuring weirs in rocky stream beds with the water at high stage need not be reminded of the difficulty in making the structure water-tight, especially at the junction with the stream bed. The volume of finer materials required to complete the dam that holds back a depth of water of only 2 or 3 ft., may be doubled or trebled, because of the persistent erosion and loss of the finer particles through the rock-fill.

The extensive studies and writings of the author on the utilization of various Western rivers, and his location of the most feasible dam sites and storage basins, are valuable contributions to professional knowledge.

Referring to Conclusion No. 9, "Should either the rock-fill or a concrete dam be overtopped by a flood, the damage might be sufficient to cause failure", it seems improbable that a concrete structure of such magnitude would be designed or constructed so as to permit failure if overtopped, whereas the rock-fill would certainly be lost under such a condition, and the resulting damage and loss in the lower valleys would be incalculable.

In view of these considerations and the uncertainties that would envelop the construction, the cost, and the behavior of the rock-fill dam as proposed, it seems a safe conclusion that any dam of unprecedented height at the proposed or similar sites will be of masonry, founded on bed-rock, or of rock-fill with adequate core-wall.

SAMUEL FORTIER,* M. AM. SOC. C. E. (by letter).—The people of the West are much interested in feasible plans to utilize the waters of the Colorado River. Even a partial utilization of this river might affect for good or ill the citizens of seven Western States. Perhaps the most valuable part of the author's paper on this subject is in outlining the wonderful potentialities of this river, when properly controlled, in furnishing water for irrigation, producing energy, and protecting fertile lands from floods. He might have added a fourth, namely, the settlement and retention of the river sediment within the natural channel of the river.

For several years, the U. S. Bureau of Public Roads, under the direction of the late C. E. Tait, M. Am. Soc. C. E., has been carrying on an investigation of the silt problem of the Colorado River, in co-operation with the State of California and the irrigation interests of the Imperial Valley of California. As a part of this investigation, daily samples were taken at Hanlon Station, the river intake of the Imperial Canal System, from July 1st, 1917, to June 30th, 1918, to determine the percentages of silt entering the System from the river. These percentages were ascertained by filtering out and weighing the solids contained in the muddy water of each sample.

In Table 4 is given the maximum, minimum, and average daily percentages by weight for each month of the period covered.

Owing to the uncertainty in ascertaining when silt has reached its least volume in the process of consolidation, it is more difficult to express with the same degree of accuracy the percentage of silt by volume. From October, 1907 to September, 1908, samples of equal volume were taken daily from the turbulent water below the gates at a number of stations of the Imperial Canal System and poured into one container for each calendar month. The composite samples thus obtained were then shaken and settled for 30 days in glass tubes, 1 m. high, after which the percentage of silt was noted. The results obtained on the Main Canal at Hanlon Head-gate was a maximum of 3.8% in August, a minimum of 0.9% in July, and a mean for the year of 1.6 per cent. If due allowance is made for differences in the quantity of silt carried in 1907-08 and 1917-18, a percentage of 1.6 by volume would compare in a general way with a percentage of 0.242 by weight.

* Associate Chf., Div. of Agricultural Eng., Bureau of Public Roads, U. S. Dept. of Agriculture, Berkeley, Calif.

In 1919, there was delivered to the Imperial Irrigation District 1 584 312 acre-ft. of water diverted from the Colorado River, and this quantity of water was applied to 413 440 acres of land. These figures do not include the quantity of water delivered to lands in the Republic of Mexico, served by the same system. In that year, the cost to the Irrigation District and to the several subsidiary companies known as mutual water companies for removing silt from the canals, amounted to approximately $1 000 000. This cost did not include that incurred by the farmers in removing silt from farm laterals, damages to crops as a result of silt, or modifications necessary on account of yearly accumulations of silt on cropped fields. This extra cost incurred by the farmers may be conservatively estimated at $2.00 per acre per annum, thus bringing the total damages caused by silt in one year to $4.42 per acre irrigated.

June, 1918	0.269	0.019	0.061
Mean			0.242

If it is true, as reported, that 1 220 000 acres are irrigable from the lower part of the Colorado River, the damage caused by silt in one form or another, unless much better controlled than at present, would impose yearly a heavy financial burden on the part of the water users.

It is evident, therefore, from what has been stated, that the waters of the Colorado River should be stored not only to provide water for irrigation, develop power, and prevent floods, but also to retain the river silt. The cost of such storage on a large scale by concrete dams is not likely to exceed $2.25 per acre-ft. The quantity of water required to irrigate such crops as are grown on the Lower Colorado Basin is usually less than 3 acre-ft. per acre, measured at farmers' deliveries. Accordingly, the first cost of storing enough water to irrigate 1 acre of land in this Basin, exclusive of transmission losses, would be about $6.75, as compared with $4.42, the present annual cost of removing silt from channels and compensating land-owners for the injurious effects of depositions of silt on irrigated land.

It will be noted by a reference to Table 4, that the average percentage of silt by weight is 0.242. The waters of the Colorado River at Yuma, Ariz., contain slightly more than double this quantity, or 0.5 per cent. The differ-

ence is due to skimming and other processes by which the water admitted to the main canal of the Imperial System is rendered freer of solid matter.

As to the author's tentative plan to store water at Lees Ferry, the writer regrets that he cannot approve of the site selected or the plan proposed. The site is too far removed from available irrigable lands, settled communities, or transportation facilities. Owing to the long distances between the dam site and the markets for power, only a small percentage of the hydro-electric energy which might be developed could be utilized. Besides, as the writer has tried to point out, the retention of silt is an important factor in storing water, and by locating the reservoir at Lees Ferry the tributaries which carry the largest quantity of silt would enter the main river below the reservoir.

As regards the author's tentative design for a rock-fill dam in the channel of the Colorado River at Lees Ferry, the feasibility of blasting enormous quantities of rock at a low unit cost into the channel from the adjacent side-walls in the manner proposed will not be questioned. To render water-tight such a quantity of blasted rock so placed, in the writer's opinion, would be impractical in any such manner as that proposed. The author states that the loose rock in the dam would be about 15% greater than the space occupied by the same material in its natural compact state. This is evidently an error, as authorities are agreed that when 1 cu. yd. of solid stone is broken into pieces, it will occupy when loose about 1.9 cu. yd. In other words, the voids in broken rock generally run from 40 to 50 per cent. In blasting rock in the manner proposed, a fairly large percentage would be thrown into the river gorge in large, irregularly shaped masses, some of which might contain 1 500 cu. yd. When piled up on the site of the dam, these large masses would contain correspondingly large open spaces. There is a further possibility that these large open spaces would be connected, thus permitting large quantities of water to pass through, especially if the water was under high pressure. The author proposes to render such a mass of loose rock water-tight, first by sluicing in broken rock varying in size from 1 in. to 6 in., followed by the sluicing of sand. The bulk of such rock could not well enter the larger cavities, except through the transporting power of the water. So little could be done to control the action of the water in moving the smaller rock particles from cavity to cavity that the element of chance assumes large proportions. In fact, the whole procedure would be a game of chance. Perhaps the rock particles might find a lodging place, and then, again, perhaps they might be borne through the structure by the force of high heads of water. In any event, the greatest efficiency that could be expected would be that a relatively small part of the voids in the rock-fill could be filled in this way. The author also proposes to sluice sand into the open spaces when the latter are filled with broken rock. The use of sand, however, is based on the belief that the cavities would first be filled with the smaller broken rock. Otherwise, the sand would be transported through the rock-fill.

A Combination Concrete and Rock-Fill Gravity Dam.—Although the writer believes that it would be unsafe as well as unwise to build a loose rock-fill dam in the manner outlined, and that if a dam is built in Boulder Canyon, or elsewhere on the Colorado River, it will be of concrete through-

out, he is of the opinion that a certain percentage of loose rock, having the open spaces well filled with finer material, might well form part of a concrete gravity dam of the dimensions under consideration. The foundation of a combination structure of this type, up to the natural high-water elevation, would be laid in concrete in the manner customary in building gravity dams, but the superstructure would consist of massive concrete walls enclosing compartments filled with broken rock, gravel, sand, and rock dust. By exercising care in grading and in placing the rock materials, the specific gravity of the loose rock in place could be made to approach 80% of that of the concrete, whereas the cost per unit of volume of rock-fill in place, as compared with concrete in place, would be about as 1:3.

This suggestion is merely a new adaptation of an old idea. From the days of the Pilgrim Fathers, the pioneers of every State in the Union have made use of wooden crib-dams filled with rock. Unless the native logs or sawn timbers, of which the cribs are built, are continuously submerged, early decay is inevitable. In these days of higher cost of timber, as compared with that of concrete, this old type of pioneer dam might well receive renewed attention, providing concrete, either plain or reinforced, can be used in lieu of timber. For example, some advantages in the way of lessened cost might be derived in using this combination structure for relatively low diversion dams by building on a secure foundation a skeleton structure of reinforced concrete, enclosing compartments to be filled with loose rock. At the other extreme, as regards the height and other dimensions of dams, is to be found such a structure as is contemplated for one of the canyons of the Colorado River. Nothing approaching any such structure in size has ever been built, and the internal stresses produced by the setting of the concrete and changes in temperature would be more or less conjectural; whereas in building what might be termed a skeleton dam of concrete, but of ample strength, the thickness of the several longitudinal ribs would be well within established practice. The general form of such a type of dam would not differ materially from the common gravity type, except that the dimensions would have to be increased to take care of the lesser specific gravity of the loose-rock portion as compared with concrete. The up-stream face would also consist of a series of sharp arches abutting against the vertical longitudinal ribs and against the side-walls of the canyon. These ribs, in turn, would be tied into arched cross-ribs, thus enclosing compartments of the general form of the frustum of an inverted pyramid. Such a form would tend to wedge in and compress the loose rock placed therein. A drain to bed-rock could be installed in the base of each compartment, and provision made to drain each compartment. There would be no horizontal partitions in any compartment, but the top of each might be sealed with reinforced concrete if found to be desirable.

The main advantage in using loose rock in conjunction with concrete, in a dam of the kind proposed, lies in the lessened cost. If such a structure could be designed to consist of 40% loose rock, the saving in first cost would be considerable. Other minor advantages might lie in greater elasticity and better facilities for expansion and contraction joints and draining the

foundation. The reduced shearing strength along horizontal planes and the difficulty in designing safe multiple arches on the up-stream face, however, might prove disadvantageous.

L. F. HARZA,* M. AM. SOC. C. E. (by letter).—The author proposes to build a dam about twice as high as any yet constructed, and of a type which as yet has been applied to a height only one-half as great as other types. The method proposed has been applied only to very small and unimportant or temporary dams of that type, and contemplates the formation of a storage reservoir that would be as large, if not larger, than any in existence, with valuable lands and human habitations in the lower reaches of the river. Whether such a project should be undertaken with the present knowledge of such structures hardly deserves serious consideration. Man has never been able to advance safely in the science of engineering by such stupendous strides, and this work, if it is undertaken, calls for the maximum degree of safety which engineering knowledge can provide.

As a hypothetical problem, however, serving by its very size to intensify the study and discussion of this type of structure, it should prove valuable in bringing out all the experiences, theories, and opinions bearing on this type of dam, for subsequent application to smaller structures.

In 1914, the writer proposed such a plan, on a smaller scale, as one of several alternative plans, although not the favored one, for closing the main channel of the Columbia River near The Dalles, Ore., after having completed a by-pass channel and gates of sufficient size to pass and control the entire flood flow.†

In this instance, the available rock-fill material was partly to be piled for this purpose behind large rubble retaining walls and was assumed to cleave on a plane inclined on a slope of 1 on 1, after the blasting of the retaining walls, thus furnishing sufficient material (about 900 000 cu. yd.) above this slope to divert the river completely.

The writer knows of one instance where a blast on a smaller scale was used to close a narrow river gorge under a head of about 100 ft. Subsequent attempts, extending over about 7 years, to seal this rock-fill with fine material have not proved successful, unless it has been accomplished recently. Local settlements of the fill occur periodically, which settle and crack the blanket of fine material, starting channels of flow which quickly enlarge until a hopper-like cavity forms in the blanket, through which water escapes freely into the coarse rock.

The writer believes that the principles which should determine the design of the blanket to tighten such a rock-fill dam are:

(*a*).—The material must be graded from coarse to fine by such gradual transition and by such definite and controllable means, that each size of material will be continuous over the whole surface and will be too coarse to be carried away through the pores of the next larger size.

* Cons. Hydro-Elec. and Hydr. Engr., Chicago, Ill.

† "The Columbia River Power Project," Technical Publishing Co., San Francisco, Calif.

(*b*).—That each layer must be of sufficient thickness to preclude the possibility of local settlements of the supporting rock that would cause fault slips in this blanket sufficient to bring the fine material in contact with material coarse enough to permit the fine material to be carried away by percolating water, and thus destroy the blanket locally.

(*c*).—Or, preferably, that the earth blanket, in addition to Requirement (*a*), should also be of the full thickness of an earth dam if standing alone and unsupported by the rock-fill, in order that the velocity of the seepage may be comparable to that in earth dams.

Obviously, Requirements (*a*) and (*b*) are difficult or impracticable of accomplishment when material is deposited under water on an irregular surface, as would be the case if the rock-fill was formed by a large blast from the adjacent walls. It might be argued that the natural process of percolation would eventually segregate the materials as demanded by Requirement (*a*). This, however, would require many years of repairing blow-outs, settlements, and cavities formed by the carrying out of material, before equilibrium would be established, if indeed it ever would be.

Requirement (*c*), if the up-stream slope of the rock-fill was 2:1, might result in a slope of about 7:1 or 8:1 for the final up-stream surface.

If an earth dam at full section was to be built up stream from the rock-fill, its foundation would require the same treatment, prior to the blast, that would be given to an earth dam constructed by the usual means. This would require under-flow cut-offs to bed-rock, the grouting of all fissures in the bottom and side-walls to be covered by the fill, and a liberal number of concrete cut-off walls in the bottom and sides of the gorge to prevent seepage along the contact between the earth and the rock, which otherwise might cause channels that eventually would threaten the safety of the structure.

The writer would like to cite certain observations bearing on the principles of the proposed type of dam. In British Columbia, there is a narrow canyon, through which a river flows with a flood of about 50 000 sec-ft. and with a fall of about 50 ft. per mile. Just above a narrow section, flanked with steep mountains about 8 000 ft. high, the river becomes suddenly sluggish and meanders through an alluvial plain that is about ½ mile wide and 30 miles long and as flat and marshy as any point along the Mississippi. The mountains rise abruptly on each side of this marshy plain, forming a section of valley like a "V," with a straight horizontal line half way up. This condition strongly suggests a natural dam formed by faulting or by a landslide at the transition from the marshy valley to the roaring canyon. Borings have proved it to be of landslide origin. Here is a natural rock-fill dam acting as its own spillway, which has been silted successfully by natural process. The down-stream slope, however, is about 100 : 1, and the silt blanket has filled the reservoir.

The writer studied and reported* on another such instance in 1915, that of the Cascade Rapids in the Columbia River. He refers to this report because it conveys a lesson in conflict with opinions expressed in some of the

* *Bulletin No. 5*, State Engr. of Oregon.

discussions. The statement has been made that it would be difficult to reach the center of the fill with rock from the two walls. Undoubtedly, this would be the case if the rock was blasted to its resting place. If, however, it is merely dislodged along a cleavage plane so steep that the whole mass would tend to slide, the writer is not sure but that the center of the dam would be the highest.

The rock slide of the Cascade Rapids from an elevation of 3 420 ft. appears to have buried a river 1 mile away and diverted it to a new channel about 3 miles away, of which the detritus still forms the northern bank. Perhaps this is the result of the inertia of the slide and of a subsequent movement on a slippery bed. The writer also remembers having observed small avalanches with the outer nose of the detritus piled higher than that part closer to the mountain, or, at least, it so appeared without an instrument. So many plans for dams like that of the author, but on a smaller scale, have been proposed that it seems to be the natural impulse of almost every engineer, when he sees a narrow, deep canyon, to want to build a dam by the rock-slide method.

I. GUTMANN,* ASSOC. M. AM. SOC. C. E. (by letter).—It has been suggested by Mr. Muckleston that there is an analogy between the rock-fill dam, proposed by Mr. La Rue, and a natural landslip, which, in 1893, dammed the Birahi-Ganga, in India, and formed Gonha Lake. It may seem strange to compare the dam, which is proposed to be built by blasting rock from solid canyon walls, to a pile of rock formed by a natural landslip. The analogy, however, appears most appropriate and highly impressive after one learns, from the references pointed out by Mr. Muckleston, the following details of paramount importance:

1.—That the Birahi-Ganga landslip consisted of enormous masses of limestone and Dolomite rocks, mixed with detritus and covered with a "thick layer of white impalpable powder."

2.—That the rocks sheared off from a steep hill and dropped from a height of 4 000 ft. above the bed of the stream.

3.—That the 900-ft. dam thus formed stood for about a year until it was overtopped.†

There seems to be sufficient mechanical similarity between slides of this type and the new method of dam construction suggested by Mr. La Rue, to justify further reports and studies of dams formed by natural landslips.

The writer can cite a similar occurrence, on a much smaller scale, which took place on the Jordan River, in Palestine, on December 8th, 1267. According to an Arab chronicle,‡ a hill on the west bank, near Damiah, fell into the river and kept it completely dammed for sixteen hours. The Jordan was in full flood at the time. From a direct knowledge of the river, the writer would think that the river may have carried from 2 000 to 3 000 sec-ft. The natural dam must have been composed of alluvial and diluvial earths.

E. C. La Rue,* M. Am. Soc. C. E. (by letter.)—The writer's paper was prepared before detailed surveys had been made of the Lees Ferry project. It was necessary, therefore, to estimate the capacity of the reservoir, the depth to bed-rock, distance between canyon walls at the dam site, length of spillway tunnel, etc. The results of detailed surveys and diamond drill borings are now available, and it is believed that definite information relating to the Lees Ferry project will be of interest. Table 5 gives the figures disclosed by the survey in comparison with those estimated by the writer.

TABLE 5.—Data Relating to the Lees Ferry Project.
(Preliminary Estimates and Data Disclosed by Surveys.)

	Preliminary estimate.	Data disclosed by surveys.
Width of canyon at water surface, in feet	450	430
Width of canyon at Elevation 720 above water surface at dam site, in feet	1 000	1 600
Width of canyon at top, in feet	1 800	1 900
Length of spillway at Elevation 200 above water surface, in feet	3 000	2 900
Storage capacity of reservoir at Elevation 700 above low-water level, in acre-feet	50 000 000	54 000 000
Capacity of reservoir between Elevations 600 and 700 above low water, in acre-feet	20 000 000	21 000 000
Depth of bed-rock in river channel at dam site, in feet	100	Less than 100

The greatest error was made in estimating the width of the canyon at Elevation 720 above the water surface at the dam site, the writer's estimate being 1 000 ft., whereas the correct distance is 1 600 ft. The writer's estimate of the width of the canyon at the top was nearly correct, which indicates that the upper face of the canyon walls is more nearly vertical than was assumed. The volume of the rock-fill dam would be greater, but the conditions for blasting the material from the upper part of the canyon walls are more favorable owing to the fact that the upper face of the wall is nearly vertical.

Those who have studied the paper have gained the impression that the writer was advocating, a 700-ft. dam at Lees Ferry to store 50 000 000 acre-ft. of water as a project feasible of construction at this time. The primary purpose of the paper was to bring out engineering opinion on the practicability of constructing a dam such as that described. The Lees Ferry site was selected in order to illustrate the methods of construction suggested, because it was well known to the writer and seemed to offer unusually favorable conditions for the building of such a dam. The writer was not and is not advocating the Lees Ferry project or any other specific project on the Colorado River as the proper one to be developed at this time. During the past seven years, he has frequently stated that before any money is spent on the construction of a high dam on the Lower Colorado, an investigation of all possibilities should be made, and a report should be prepared by competent engineers, outlining a comprehensive plan for the development of the Colorado River Basin from Wyoming to the Gulf of California. He has also explained that the first large project to be undertaken on the lower river, should be a unit of a carefully prepared compre-

* Hydr. Engr., U. S. Geological Survey, Pasadena, Calif.

hensive plan for the development of the whole basin. In the writer's opinion, sufficient information is not available to form the basis for such a comprehensive report, and he will state further that no report based on detailed engineering data has ever been prepared to show the most economical plan for the development of the Colorado River below the mouth of Green River.

When complete data are available, an intelligent conclusion can be reached as to whether it will prove most economical to develop the first large flood-control reservoir at Lees Ferry or elsewhere. It will then be possible to evaluate properly the advantages of creating a storage reservoir where it will control this great river for comprehensive power development through a fall of more than 2 000 ft. and simplify the spillway plans and construction problems of eight or ten dams, and where it will afford adequate regulation for irrigation and the prevention of flood damage, and weigh them against the advantages of a reservoir that may control 10% more water at the foot of the power section of the river and only half as far from the principal area of irrigable and flood-threatened lands. The real value of creating a storage reservoir at the head of the fall at Elevation 3100, which would make possible the development of between 3 000 000 and 4 000 000 h. p. between Lees Ferry and Black Canyon, and result in a saving of millions of dollars in the construction cost of all dams built in the river below, would be disclosed.

Mr. Coutlee has called attention to a number of rock-fill dams in Canada. It is interesting to note that a rock slide, 2 miles long and 2 miles wide, on Old Man River did not act as a water-tight barrier, it being stated that without gathering much head the small river was able to seep through the dam. Mr. Coutlee appears, however, to hold the opinion that satisfactory results can be obtained by the construction of dams of the rock-fill type.

Mr. Muckleston calls attention to a natural rock slide that occurred in 1893 on the Birahi-Ganga, a small stream in India. Although this natural dam was 900 ft. high, 11 000 ft. wide at the base, and 2 000 ft. wide at the top, Mr. Muckleston states: "Nevertheless, the dam went out as soon as it was topped." He failed to state that the natural dam had no spillway and that due to this fact it was known that the dam would fail.

The writer believes that the paper describing the failure of the Gohna Lake Dam contains information of great value to engineers interested in determining the feasibility of constructing high rock-fill dams. The following quotation was taken from a paper entitled "The Great Landslip at Gohna, in Garhwal, and the Measures Adopted to Prevent Serious Loss of Life",* by J. H. Glass, Chief Engineer and Secretary of the Department of Public Works of Bengal:

"On the 19th of November, 1893, the first intimation of the Gohna landslip reached the Government. * * * The district authorities had heard from a native source that early in the previous September an enormous mass of material from the Maithana hill had subsided into the Bireh Ganga river, completely blocking it, and that a large lake was under course of formation. For some time afterwards material continued to fall, huge blocks thundering down

* *Journal*, Soc. of Arts (Lond.), March, 1896, p. 431.

the hill, and crashing into the mass below, but there was no further fall of any size till about the end of October, when a great slice of the hill moved forward into the valley, making an effective barrier of enormous proportions, and completely obstructing the flow of the river. The falling mass was accompanied by a deafening noise, and the neighborhood for miles around was filled by clouds of dust, which whitened the ground and tree branches like snow. Gohna is situated away from any road route, and is most difficult of access, so that it was not possible to obtain readily any accurate account of what had really happened. * * *

"The result of Colonel Pulford's inspection was made known to Government in a semi-official letter, dated the 21st December. He reported that the mass of earth and rock composing the landslip was about 900 ft. in height, 2 000 ft. across at top, 11 000 ft. at the base along the valley, and 3 000 ft. at top and 600 ft. at bottom across the valley. These figures give an idea of the magnitude of the slip. It was largely composed of enormous masses of rock, some of which, lying on the surface, were calculated to be many tons in weight, with an admixture of detritus and a thick layer of white impalpable powder over all. The slip had taken place from a precipitous hill bordering the river on the right bank. The hill, which is called Maithana, has an elevation at the summit of about 11 000 ft. above sea-level, and the part from which the fall occurred is about 4 000 ft. above the bed of the stream. The force of the fall from so great a height as 4 000 ft. carried the rocks and *débris* right across the valley of the river, and for some distance up the steeply scarped hill on the left bank; then, its energy expended, the mass slipped back into the valley, forming a dam, with a big slope up against the hill on the left bank. The further great slip in October filled up the dam on the right bank against the hill on that side, in such a manner that the top of the dam had a large depression some 150 ft. below two sloping mounds of rock and *débris*.

"The bed of the Bireh Ganga river slopes at about 250 ft. per mile at Gohna, and is the bottom of a narrow gorge, with steep, and sometimes precipitous sides. The gentler slopes of the hills are grass-covered at the base, and, higher up, are clothed with evergreen, oak, fir, and rhododendrons. Immediately below the slip, the course of the river turns nearly at right angles, and passes through a narrow gorge with precipitous sides of rock. In the more open parts of the valley, the slopes are terraced, with great labour, for cultivation; but the configuration of the ground and the nature of the soil are such as to prohibit any large amount of cultivation. The river basin at Gohna, draining into the lake formed by the landslip, has an area of about 90 miles, and is bounded on the north and east by a snow-clad ridge of the Himalayas, rising to an altitude of 21 200 ft. above sea-level. A large portion, therefore, of the water of the river is derived from the melting of the snows, and this supply is, of course, at its greatest during the hot season. * * *

"From the information then before him, Colonel Pulford fixed the date on which the water would rise to the top of the dam as the middle of May. Later on, however, when data in regard to the area enclosed by the landslip, and in respect to the rainfall and snowfall during the year over the catchment area of the river had been collected by the Public Works Officer who was sent to Gohna for that purpose, Colonel Pulford reported that the lake would probably overflow about the middle of August; and the 15th of August was accordingly adopted as the date by which all arrangements for dealing with the flood should be in working order. * * *

"Before the end of July all the arrangements which had been ordered for the protection of life and property were completed. A good deal of percolation was noticeable at the toe of the dam. * * * The area of the lake when the water was level with the top of the dam was calculated from the contoured map prepared by Lieutenant Crookshank, R. E., to be about 37 000 000 sq. ft.

in round numbers, or say 1¼ sq. miles, and the total contents were roughly estimated at 16 650 000 000 cu. ft. * * *

"The first symptom of the approaching collapse occurred on the 10th August. For some time past the water had been rising very steadily, owing to the rains which had commenced early in June and the melting of the snows, and on the 4th August it had reached within 82 ft. of the lowest part of the dam. On the 9th August there was a very heavy rain which caused a serious slip in the down-stream face of the dam, leaving an almost perpendicular section some 400 ft. high. The section thus exposed disclosed a layer of stones at the top, below which only pulverized rock was visible. Percolation, which was now very heavy, was running in a considerable stream over the boulders of the former river-bed laid bare by the slip referred to. This slip caused the death of a man called the Gohna Fakir, his wife and three children. * * * On the 11th August the first warning was telegraphed to all concerned, intimating that the lake would escape within fifteen days' time; and this was followed by a notice that the lake was 50 ft. from the top of the dam. In all 87 warning messages were despatched from Gohna. Percolation was still steadily increasing. On the 10th July it was calculated to be 50 cu. ft. per sec., on the 17th July, 150 cu. ft., and on the 12th August, 350 cu. ft. per sec. On the 22nd August, Lieut. Crookshank issued the warning message that the lake was expected to escape within 48 hours. By cutting a very narrow channel 2 ft. 6 in. deep in the crest of the dam he expected to bring in the flood early on the morning of the 24th August, but owing to increased percolation and smaller rainfall than on previous days, the lake rose so slowly that it did not reach the bottom of the cutting until the afternoon, and as it was considered important that the flood should occur during day-light, the channel was filled up so that the over-topping might take place on the morning of the 25th idem. The lake water commenced to trickle over the dam through the cutting at 6.35 A. M. on the 25th August. At first the destructive action of the water was very slow, and the volume escaping from the lake over the dam did not exceed 200 cu. ft. per sec. up to 3.30 P. M., at which time a thick mist descended and heavy rain fell preventing Lieut. Crookshank from taking further observations. But at 2 P. M., the percolation which had now increased to an alarming extent, caused a sudden cutting back of the dam on the down-stream side to within 1 000 ft. of the overflow point. At 2.30 P. M., a message had been despatched down the line to the effect that the dam was cutting back, and that the lake was expected to commence falling during the night. The thick mist and heavy rain still continued to obscure the slip, and it was quite impossible to observe the action of the water on the dam. At 11.30 P. M., a loud crash was heard, and in spite of the mist and rain the air was filled with a fine dust which rose from the dam. On observing this, Lieut. Crookshank went with the civil functionary, Palwari Mali Dasauli, down to the dam, and made a final inspection of its condition. It was then midnight. As far as he could ascertain the dam was completely breached, and the lake water was escaping through a rapidly increasing channel. The effect on the dam had already been very marked, and the upper surface where Lieut. Crookshank and the Palwari were standing suddenly sank some feet. At twenty minutes after midnight another warning message was sent down the line to the effect that a very great rush of water was being discharged from the lake. It was not possible to gauge the discharge owing to the thick mist which prevailed and the torrents of rain which were falling, nor could it be ascertained at what rate the lake was emptying. At 5 A. M., although the valley was full of mist and the light very scanty, it became evident that a great fall had taken place in the level of the lake, and the irrigation officers and civil authorities at Hardwar were warned to expect a great flood. The sides of the lake, after it had emptied below high-water mark, were waste and desolate. They were cracked and had slipped in many places, and were devoid of trees and vegetation, and an offensive smell

rose from the ground which had been so long submerged. Below the dam, the valley of the Bireh Ganga was filled up with the huge blocks of rock, washed away from the landslip by the torrent, and it was found that at the gorge below Gohna, the level of the bed of the stream had been raised about 234 ft. The discharge from the lake was still going on, but was confined to the natural drainage of the river basin. In emptying itself of so large a part of its contents, the lake had made a strong and substantial weir, composed of huge blocks of rock, tightly packed with boulders, and having a long gentle slope stretching far down the valley. The first rush of the impounded water commenced about 11.30 on the night of 25th August, and by 4 o'clock on the following morning the lake level had fallen 390 ft., equivalent, in round numbers, to a discharge of about ten thousand millions of cubic feet in the space of four and a half hours. At Chamoli, a village some 13 miles from Gohna, the flood first began to rise at 11.55 on the 25th August, and the maximum height attained was about 160 ft. above ordinary flood level. The abutments of the permanent bridge, a temple, the Dharmsala, Bazar, and Dispensary, were completely washed away, and the bed of the river was raised about 50 ft. with the *débris* deposited by the flood. * * *

"The large rocks and *débris* of the landslip have been so consolidated and packed by the flood that they now form a massive and solid dam, which is not likely ever to be disturbed, and a permanent lake has probably been established at Gohna. The dimensions of this lake are as follows: Greatest length about 3 900 yd., average width, 400 yd., and greatest depth 300 ft. It may be that in time Gohna will become a pleasant resort for the weary traveller from the plains, and that boats will sail upon the lake. But it will be long before then!"

Data regarding the Gohna Lake Dam are given in Fig. 14. Fig. 15 shows the variation in the seepage through the dam as the head of water on the dam increased. In the paper describing the Gohna Lake landslip, a landslip on the lower face of the dam is mentioned, which it was stated was caused by a heavy rain. When this slip occurred, the head of water on the dam was about 840 ft. It is the writer's opinion that the slip was what is commonly called a "blow out." No doubt the down-stream section of the natural dam was too tight to permit free drainage of seepage water. However, it should be noted that even after the blow-out occurred the dam did not fail until it was actually overtopped. This dam would be standing to-day if there had been adequate spillway, and conditions favorable for free drainage in the down-stream part of the dam.

Although regretting that Mr. Warner, instead of presenting serious discussion based on his many years of experience, has limited himself largely to facetious criticism, the writer finds solace in the apparently unqualified approval given to the suggested rock-fill dam in the following sentence:

"The present and future value of property below Lees Ferry makes imperative the adoption of a dam of the gravity type [and it must be admitted that a rock-fill dam pre-eminently conforms to this specification], because it is the only type which will have the approval of the farmer, the bond-buyer's engineer, and the Federal and State regulatory bodies."

Mr. Noetzli holds the opinion that if the loose rock-fill were overtopped during construction by a flood of 100 000 sec-ft., only "a few of the largest blocks of the dam would stay within the area of the foundation." To support his opinion, he calls attention to the fact that the Lower Otay rock-fill dam was swept away when overtopped by a flood in 1916. The Lower Otay Dam

had a steel core supported by loose rock laid to a slope of 1½ : 1 on both the up-stream and the down-stream face. If this rock-fill had been constructed with its down-stream face on a slope of 14 : 1, it seems probable that, after the failure, some of the material would have been found within the original area of the base of the dam. At Elevation 250, the proposed rock-fill dam at Lees Ferry would have a down-stream slope of 14 : 1. However, precaution should be taken to prevent a flood from passing over the rock-fill either during construction or after the completion of the dam.

Mr. Noetzli apparently is not opposed to the rock-fill type of dam if means other than those suggested by the writer are used to make the dam water-tight. As Chairman of the Arizona Engineering Commission, the writer visited the site of the Parker Dam on the Colorado River and believes that a safe dam

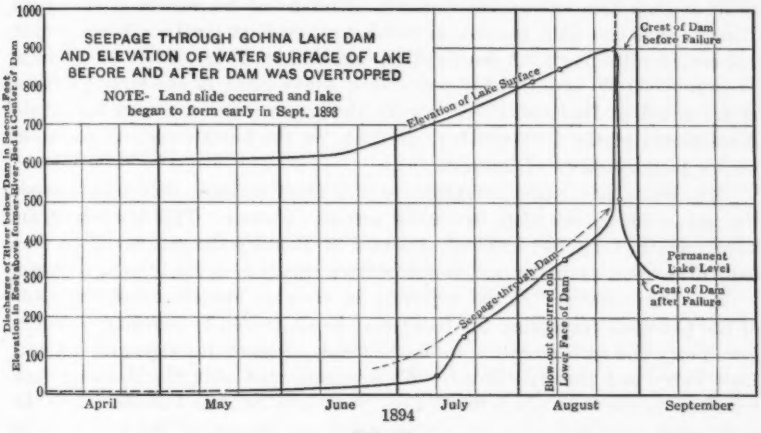

FIG. 15.

of the height proposed by Mr. Noetzli can be built at that point at reasonable cost. The combination concrete rock-fill dam proposed by Mr. Noetzli for the Parker site may be the proper solution of the problem.

The writer wishes to express his appreciation of the discussion prepared by Mr. Bryan giving the geological setting of the Lees Ferry dam site. The data submitted by Mr. Bryan will prove of value to the engineers who are finally called on to determine the most feasible type of dam to build at that site.

In proposing to build the dam to a height of 250 ft. with the first blast, the writer was of the opinion that the rock-fill would displace the fine sand and silt and settle to the layer of sand and boulders. It might be safer, as a first step, to blast a smaller quantity of material into the river, allowing the flood water to wash out the fine material which would cause the rock-fill to settle to a firm foundation. This change of plan would meet one objection mentioned by Mr. Davis, who suggests a concrete pavement cemented to the abutment walls to prevent leakage between the rock-fill and the canyon walls. Owing to vertical jointing, the canyon walls at the dam site are not smooth. If leakage

should occur between the rock-fill and the abutment walls, the water must travel a comparatively long distance, perhaps 1½ miles near the base of the dam. It does not seem reasonable to believe that such leakage would take place if the voids in the loose rock can be filled with a fine material.

Unfortunately, Mr. Davis has assumed that the writer holds the opinion that a dam 780 ft. high should be built as a first step in the plan to control the flood flow. A dam to raise the water 700 ft. was chosen, because it is what may be considered the maximum development feasible at the Lees Ferry site. A higher dam would affect the dam proposed below the mouth of Green River. The writer's opinion on this matter is, that no engineer is justified in presenting a project for flood control as being the most feasible, until he has first collected the necessary engineering data to show the possibilities for development at each dam site on the Colorado River below the mouth of the Green River. Sufficient data are now available to show that the Lees Ferry project has considerable merit. A flood-control dam at Lees Ferry, about 400 ft. high, to store 8 000 000 acre-ft. of water, with a power plant in the Grand Canyon at the mouth of Diamond Creek, may be the proper plan for a start toward the development of the 4 000 000 h. p. available on the lower river. A report on such a plan would be of interest.

Mr. Davis has called attention to the great damage that would result through suddenly releasing 50 000 000 acre-ft. of water. This is obvious, the same quantity of water suddenly released at Boulder Canyon would be even more disastrous, as this project is nearer the property most likely to be damaged.

Mr. Davis states that the writer is in error in claiming that the floods of the Colorado (excepting the Gila) may be controlled by building a dam at Lees Ferry and calls attention to the 50 000 sq. miles of drainage area between Lees Ferry and the Gila River. We are concerned with the drainage area tributary to the Colorado between Lees Ferry and Boulder Canyon. It is the flood water contributed by this drainage and not the size of the basin that is important. Mr. Davis has presented no data to support his contention that dangerous floods originate in the basin between Lees Ferry and Boulder Canyon. The Little Colorado is by far the most important tributary to the Colorado in this section. Intermittent records are available, showing the flow of this stream since 1905. The largest flood recorded is 20 200 sec-ft. In January, 1916, when the Gila discharged a flood of 200 000 sec-ft., the flow of the Little Colorado was 16 000 sec-ft. There is a feasible site on the Little Colorado where a dam to raise the water 50 ft. would make possible the regulation of the flow of this stream to 600 sec-ft., or less. Furthermore, a power dam on the Colorado at the mouth of Diamond Creek would smooth out any flood that may reasonably be expected from the Paria, Little Colorado, or Kanab Creek. There is no record of a flood from the Virgin River, that would endanger property on the Lower Colorado.

For a given height of dam at Lees Ferry and at Boulder Canyon, the greater storage capacity may be had at Lees Ferry. In Table 3, Mr. Davis gives, under the heading, "Boulder Canyon Reservoir", a capacity table which applies at the dam site in Black Canyon. The dam site in Black

Canyon is 18 miles below the site in Boulder Canyon. The writer understands that Mr. Davis recommends the construction of a dam at the Boulder Canyon site.

In regard to the loss of water by evaporation, Mr. Davis might have gone one step further in order to show the evaporation that would take place if the Boulder Canyon site were to be developed. Evaporation at Boulder Canyon would be greater than at Lees Ferry for a given area of water surface. With equal storage capacity at Lees Ferry and Boulder Canyon, the loss due to evaporation would be practically the same.

Mr. Davis correctly states that the underground conditions at the Lees Ferry dam site are unknown and that these conditions at Boulder Canyon have been carefully investigated. More than $200 000 has been made available for the investigation of the Lower Colorado, nearly all which has been spent at Boulder and Black Canyons.

As the depth to bed-rock at the Lees Ferry dam site is considerably less than 100 ft., the suggestion made by Messrs. Stevens and Fortier are worthy of further consideration. With bed-rock comparatively near the surface and the condition for unwatering the site favorable, the writer has changed his opinion with reference to the plan for making the rock-fill water-tight. It seems probable that a feasible plan for a combination concrete rock-fill dam can be devised.

Mr. Fortier has submitted valuable data regarding the silt problem on the Lower Colorado, but the writer cannot accept his conclusion that, in order to store a greater quantity of silt, the first flood-control dam should be built at Boulder Canyon.

The constructive criticism submitted by so many engineers is greatly appreciated by the writer, and his objective has been realized. However, he wishes to admit that it was a mistake to present for discussion a proposition to build a rock-fill dam 780 ft. in height above its foundation. The magnitude of the project seemed to stagger the imagination of the engineers who discussed the paper. A more valuable discussion would have resulted if the writer had designed a dam about 400 ft. high. The principles, however, would be the same.

If a thorough study of the physical condition on the Lower Colorado should show that the first flood-control dam should be at Lees Ferry, the time will have arrived for careful study to determine the type of dam most feasible for this site.

No doubt a board of competent engineers would give due consideration to the rock-fill type of dam as well as the concrete dam of the gravity, arch, and multiple-arch type. As the depth to bed-rock at the Lees Ferry dam site is less than 100 ft., some engineers believe that a concrete dam of the multiple-arch type would be safe and also the most economical.

Paper No. 1513

BOND STRENGTH OF WOOD PILES IN CONCRETE

By R. R. Lundahl,* Assoc. M. Am. Soc. C. E.

Synopsis

For convenience, this paper has been subdivided, as follows:

First.—The conditions are discussed, that necessitated determining the bond strength of wood piles in concrete in connection with the design of the new sewage disposal plant for Milwaukee, Wis.

Second.—A general description of the test specimens used in obtaining the results contained in this paper, together with their preparation, are given.

Third.—A detailed account, description, and discussion of each of the tests as conducted, are given.

Fourth.—The testing apparatus and the methods of testing are explained.

Fifth.—The combined results are discussed, a table of the results of all the tests is given for ease in comparison, and conclusions from the results are drawn.

General

While plans and specifications were being made by the Sewerage Commission of the City of Milwaukee for the new sewage disposal plant, the question of "the bond strength of wood piles in concrete" had to be considered.

The new plant is to be built at the eastern edge of the city, on what is now a peninsula bounded on one side by Lake Michigan and on the other two sides by the Kinnickinnic and Milwaukee Rivers, respectively. The main part of the plant is to be located on made land, within a pile bulkhead and steel sheet-piling coffer-dam, extending 1 000 ft. into Lake Michigan along the south harbor entrance pier. The coffer-dam has been built, and the area

* Asst. Engr., Milwaukee Sewerage Comm., Milwaukee, Wis.

within it has been dredged to the average elevation of the bottom of the aeration and sedimentation tanks that are to be constructed therein.

It will be necessary to place the tanks on pile foundations. With a 16-ton load on each pile, the dead weight of the tanks and the sewage, when the tanks are full, requires an average pile spacing of 5-ft. centers. The weight of the tanks, when empty, is not sufficient to overcome the buoyancy; therefore, it is necessary to anchor the structure to the pile foundation. With a 5-ft. pile spacing, the uplift on each pile averages 6 tons, and the question arose as to whether the skin friction or bond strength of a plain wooden pile in concrete was sufficient to withstand this uplift. A thorough search for information on this subject was made, but no data applicable to the conditions were found. The engineers of the Sewerage Commission favored the use of a mechanical anchorage of some type, although other engineers believed that such anchorage was unnecessary. A majority, however, seemed to favor the deformed type of mechanical anchorage, and this brought up the question of cost. The cheapest method of deforming a pile-head meant an additional cost of at least $1 per pile. As there are about 24 000 piles to be driven, this would entail a minimum additional cost of $24 000, and more elaborate methods of deformation would run as high as $2 or more per pile. This additional expense was not justified without further investigation, because there was no assurance that the deformed anchorage would serve the purpose any better than the plain pile-head. It was decided, therefore, that a series of tests should be conducted, in order to determine whether any type of mechanical anchorage was necessary, and the writer was entrusted with the carrying out of these tests. Thirteen cedar posts, ranging from 6 to 7½ in. in butt diameter, were selected for test specimens. Cedar was chosen because it was available, and it was thought that if the tests proved satisfactory on a soft wood, harder woods could be used with a considerable factor of safety. The posts which had been cut in the winter of 1919 and 1920 and stored in the open, were selected at random from a stock pile, the only requirement being that they should be straight.

The posts were prepared for thirteen types of anchorage, some of which differed only slightly. These types will be explained as the results of each test are given. The butts of the posts were cut squarely across, so that a fresh area of the ends would be exposed to the concrete, thus giving a condition similar to that when a pile is cut off at grade before it is covered with concrete. The posts were embedded 1 ft. in a slab of concrete 4 ft. square and 1 ft. thick, having a sub-slab, directly under the post, 2 ft. square and 1 ft. thick, cast with the larger slab. The object of the sub-slab was to prevent uneven curing effects around the end of the post and to give a condition similar to that obtained in practice. A 1:2:4 mixture of concrete, with washed sand and crushed gravel as the aggregate, was used. The concrete was mixed in a one-bag mixer, and conveyed in a car to a platform, from whence it was shoveled into the forms by hand. The specimens were made in the Casting Plant of the Sewerage Commission, in March, 1921. The building was heated so that there was no possible danger from freezing. The forms were extended about 6 in. above the slab, in order that the concrete might be cured

under water for 30 days, thus giving a condition similar to that to be expected in subaqueous work.

Test No. 1.—The specimen for this test was 7⅛ in. in diameter at the butt, and 7 in. at the concrete surface. The butt was immersed in water for 7 days before it was concreted. This, in the writer's opinion, was the worst condition that could obtain. The concrete was poured on March 24, 1921, and the specimen was tested on April 27, five weeks later.

In order that any movement of the concrete could be noted, the loading box was blocked up 6 in. above the slab, as shown in Fig. 1. Another box or shield was built around the post so that no frictional resistance would be caused by the material against it. The net weight per vertical foot of load in the box was 2 797 lb., the box weighed 475 lb., and the concrete anchorage 2 960 lb. The loading of the specimen to the capacity of the box was completed about 11:00 A. M., April 27, the total load being 14 760 lb. No movement had been noted at noon, but some time between noon and 2:00 P. M., the specimen failed, and as no one witnessed the failure, the time the load had been sustained, could not be determined.

The bond area of this specimen was 266 sq. in., and the failure occurred under a sustained load, for bond, of 55.5 lb. per sq. in. The results of the other tests showed that, as far as bond strength was concerned, this specimen was tested under the worst condition possible.

Test No. 2.—Specimen No. 2 was similar to Specimen No. 1, except that it was not immersed in water before it was placed in the concrete. The diameter at the butt was 6¾ in. and at the concrete surface, 6⅝ in., and the bond area was 252 sq. in.

The loading was started on May 2, 1921, the specimen having aged 5 weeks and 5 days. In order to determine the exact point of failure, the load was applied as shown in Table 1.

TABLE 1.

Load, in pounds.	Time.	Date.	Hours, load was sustained.
7 200	9:00 A.M.	May 2, 1921	6
8 300	3:00 P.M.	" 2, "	23
9 700	2:00 P.M.	" 3, "	21
10 200	11:00 A.M.	" 4, "	5
11 000	4:00 P.M.	" 4, "	19

19 500	12:00 Noon	" 13, "	1½
21 000	1:30 P.M.	" 13, "	18½

At 21 000 lb., the capacity of the crane had been reached, and this load was allowed to remain until 8:00 A. M., May 14, when the specimen was lowered and the load removed. A bond strength of 83.3 lb. per sq. in. had been developed with no sign of failure.

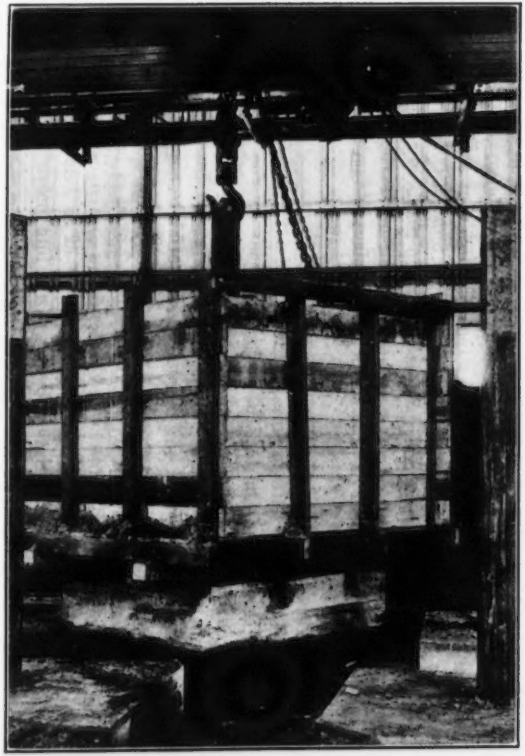

FIG. 1.—LOADING BOX BLOCKED UP 6 IN. ABOVE THE SLAB FOR TESTING.

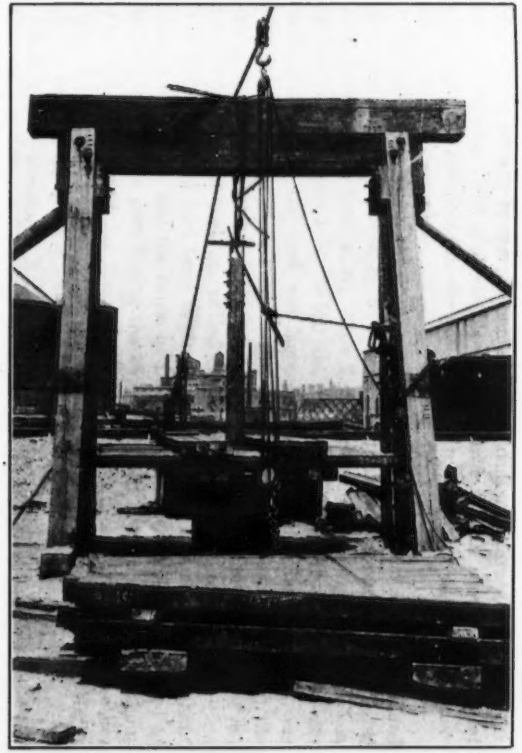

FIG. 2.—VIEW OF TESTING APPARATUS.

It was decided to move all the specimens to the open, build a gallows-frame strong enough to carry a much heavier loading, and use billet steel for loading purposes. The concrete blocks were covered with about 6 in. of wet sand to prevent shrinkage in the posts. In spite of this precaution, considerable shrinkage took place.

The test of Specimen No. 2 was resumed on June 1, 1921. A 10 200-lb. load was placed on the specimen by 5:00 P. M., and allowed to remain over night. On examination at 8:00 A. M., June 2, a slight cleavage was noted. When the load was increased to 13 000 lb., the post pulled from the concrete about $\frac{1}{8}$ in. When the load was increased to 16 000 lb., the movement was about $\frac{1}{4}$ in., but it was so gradual that it could not be observed during the loading. The load was then increased, in 360-lb. increments, to 19 500 lb., at which loading the post was pulled entirely from the concrete.

A 21 000-lb. load had been applied previously on this specimen without any sign of failure, and the cause of failure at a lesser load is attributed to the shrinkage of the post during the 18 days it had been in the open without being kept wet, except for the moisture in the sand covering. The weather during this period was exceptionally warm most of the time, and the slight rainfall drained off quickly.

Test No. 3.—Specimen No. 3 was immersed in water for 7 days before it was concreted. The diameter at the butt was $7\frac{7}{8}$ in. and, at the concrete line, $7\frac{3}{8}$ in. The concrete had aged 71 days when the loading of the specimen was started on June 2. The load was placed in 360-lb. increments and totaled 17 400 lb., at 6:30 P. M. No failure could be noted, and the load was allowed to remain until noon the following day, when it was observed that the post had pulled $\frac{1}{8}$ in. from the slab. The failure, under a sustained load of 17 400 lb., was equivalent to a bond strength of 60.6 lb. per sq. in. The load was increased to 20 300 lb., and the post pulled gradually to $\frac{1}{4}$ in., which was considered sufficient evidence of failure, and further operation was discontinued.

To guard against the conditions in Test No. 2, the remaining test specimens were thoroughly soaked, and the result of Test No. 3 shows that it was helpful.

Test No. 4.—Specimen No. 4 was dry when the concrete was poured and had aged 72 days when the loading was started at 3:30 P. M., on June 3. The diameter of the post at the butt was $7\frac{5}{8}$ in. and, at the concrete line, $7\frac{1}{4}$ in. A 16 000-lb. load had been applied by 8:30 P. M., with no indications of failure. This load was allowed to remain until 10:00 A. M., June 4, $13\frac{1}{2}$ hours, but no signs of failure were noted. The load was increased to 19 520 lb. and allowed to remain until noon, June 6, at which time the bond strength appeared to have failed slightly, but there was some doubt as to this fact. The load, therefore, was increased to 23 840 lb., at which a slight movement was noted, and, at 25 640 lb., the post had been pulled $\frac{3}{4}$ in. The specimen was now unloaded, and it was settled definitely that failure had occurred at 19 520 lb. which was equivalent to a bond strength of 69.7 lb. per sq. in.

Test No. 5.—Specimen No. 5 was 7 in. in diameter at the butt and $6\frac{1}{8}$ in. at the concrete line. The concrete was banked up about 4 in. around the post in the form of a cone. The idea was that the area of concrete in con-

tact with the pile would be increased at little added expense. This method was considered to be the next cheapest, if the results of the tests on the plain anchorages proved to be inadequate.

This specimen had aged 75 days when the loading was started at 7:45 P. M., on June 6. At 8:30 P. M., a load of 10 960 lb. had been applied, which was allowed to remain until noon on June 7, with no sign of failure. The load was then increased to 25 640 lb. by 8 000, 5 000, and 2 000-lb. increments, respectively, and at 7:00 P. M., the first sign of failure was noted. Further loading to 28 160 lb. resulted in the failure of the cedar post in tension.

If the embedded depth of the post is taken as 12 in., a bond strength of 100 lb. per sq. in. was developed. If the embedded area of the post is used, the bond strength was 75.8 lb. per sq. in. The cedar post failed in tension under a unit stress of about 850 lb. per sq. in.

Test No. 6.—Specimen No. 6 was of the same type as Specimen No. 5, but had a slightly larger butt diameter. The concrete had aged 79 days when the loading was started at 9:00 A. M. At 11:00 A. M., a load of 16 200 lb. had been applied when the first sign of failure was noted. A bond strength of only 60.0 lb. per sq. in. had been developed.

The load was increased to 23 120 lb., at which the post pulled from the concrete. The post was found to be sound, but there had been no bond to the bottom of it, whereas, in the other tests, this was not the case. The area of the bottom of the post was about 33 sq. in., and the bond on this area would have had a material affect on the total load sustained.

In the foregoing tests, the unit stresses have been calculated from the areas of the sides alone, but the bond to the bottoms undoubtedly plays an important part. The exact relation could not be determined except by tests.

When Specimen No. 6 was concreted, the post settled so that it was embedded more than 12 in. in the concrete. Accordingly, it was pulled up to the 12-in. mark. In doing this, the bond to the bottom of the post must have been destroyed. The results seem to indicate that the bond to the end fibers plays a more important part than that to the sides of the post.

Test Specimens Nos. 1 to 6

Tests Nos. 1 to 6 complete all those without any type of deformed anchorage. The conclusions from these tests are that the enlargement of the pile-head has no effect on the load sustained until the bond strength has failed. In every test, it was noted that, when the bond failed, the concrete usually dropped suddenly about $\frac{1}{8}$ in., and then continued to move slowly to $\frac{1}{4}$ in. Between the $\frac{1}{8}$ and the $\frac{1}{4}$-in. movement, the enlargement of the head became effective. In nearly every case, after this point had been reached, the load was applied without additional failure until the post either broke or pulled from the concrete.

The writer believes that as long as the concrete adheres to the bottom of the post, there is no chance for the fibers to compress. This is probably the cause of the sudden drop as soon as the bond has failed. The load necessary to overcome the bond was sufficient to compress the fibers enough to allow the concrete to drop the $\frac{1}{8}$ in. After this, an additional load was necessary to compress the fibers sufficiently to allow the post to be pulled even slightly.

A movement of $\frac{1}{8}$ in. might be injurious to a structure, and where it is necessary for the piles to withstand any upward pressure, it is unsafe, therefore, to consider anything but the bond strength of the concrete to the wood pile. It would seem safe to consider the bond strength of the concrete to the wood pile to be 50 lb. per sq. in., which value is less than any of the results obtained, but the entire static head should be used in designing, in order to obtain an additional factor of safety.

Whether a pile of larger diameter than those used would develop a similar bond strength can be determined only by tests. The Sewerage Commission intends to conduct a series of such tests, in order to secure this information.

Tests on the Deformed Specimens

Test No. 7.—Specimen No. 7 had an average butt diameter of $6\frac{3}{4}$ in. and no enlargement. Four 3-in. track spikes were driven, 90° apart, into the butt, the heads extending about 1 in. for anchorage. The concrete in this specimen had aged 80 days, and the test was started at 8:30 A. M., June 10, 1921. At 11:00 A. M., after a load of 16 640 lb. had been applied, the first sign of failure was noted, the post having pulled about $\frac{1}{8}$ in. The load was increased to 17 360 lb., and as the post continued to pull from the concrete, the test was stopped. The bond area on the sides was 257 sq. in., and the bond stress developed was 64.7 lb. per sq. in.

Test No. 8.—This specimen had a diameter of $7\frac{1}{16}$ in. and an enlargement of $\frac{7}{16}$ in. A 1-in. pin, 30 in. long, was passed through a 1-in. hole drilled through the post 6 in. from the bottom. About 1 ft. of the pin extended from each side of the post. The concrete had aged 81 days when the loading was stated at 1:45 P. M., June 10. At 4:00 P. M., a load of 18 080 lb. had been applied and no signs of failure had been noted. This load was allowed to remain until 8 A. M., June 11, when it was increased to 22 040 lb., under which, at 8:50 A. M., the first sign of failure was observed. The load was increased to 22 400 lb. and the post pulled about $\frac{1}{8}$ in., which load is equivalent to 84.4 lb. per sq. in. on the bond area.

The test was stopped, as it had already failed beyond the point of safety. No doubt, the pin through the post increased the load that could be sustained by this specimen. After the failure of the bond, which probably occurred before the line of fracture was noted, the specimen held until the fibers in contact with the pin had compressed. When this occurred, the post pulled from the concrete, and the line of failure was noted.

Test No. 9.—Specimen No. 9 had an average butt diameter of $7\frac{1}{8}$ in., and 1 ft. from the butt, it was sawed on two opposite sides to a depth of 1 in. The wedges thus formed, tapering to 1 in. at the concrete line, were then chopped out, thus making the post $7\frac{1}{8}$ in. in diameter at the butt, and, at the concrete line, a flattened ellipse, 5 by 7 in.

The concrete had aged 81 days when the loading was started at 11:30 A. M., and by 2:00 P. M., a load of 16 280 lb. had been applied when the first sign of failure was noted. The bond strength developed was 61.2 lb. per sq. in. The load was increased as follows: 17 360 lb., $\frac{1}{4}$-in. movement; 18 080 lb., $\frac{3}{8}$-in.

movement; and 18 520 lb., 1-in. movement. At 22 400 lb., the post pulled from the concrete. Examination disclosed that there had been no shearing action; the fibers had been compressed and pulled through the 5-in. hole in the concrete.

The preparation of piles in this manner would be expensive, and the results of the test show that this added expense would be unwarranted.

Test No. 10.—This specimen was 6⅝ in. in diameter and had been expanded by driving a 1 by 12 by 6½-in., hard-wood wedge flush with the butt, thus making the bottom of the post elliptical in shape, 6⅝ by 7⅝ in. Before the wedge was driven, a band was placed around the post at the concrete surface, which band was not removed during the test. This specimen was 83 days old. The load was started at 8:45 A. M., and by 11:15 A. M., the first sign of failure was noted with a load of 15 920 lb., which is equivalent to a bond strength of 63.7 lb. per sq. in. Under a load of 18 800 lb., the post had pulled ¼ in., and ⅜ in. with 20 240 lb. It was seen that this method did not increase the bond strength, and the loading was not continued.

Test No. 11.—Specimen No. 11 was trimmed to a wedge shape on four sides, instead of two sides, as was done with Specimen No. 9. The average diameter of the butt was 6½ in. and, at the concrete line, the post was about 4½ in. square.

The concrete in this specimen had aged 84 days and the first sign of failure was noted with a load of 13 760 lb. With a bond area of about 244 sq. in., this load was equivalent to 56.4 lb. per sq. in. From this result, it is obvious that the trimming of a pile-head to this shape would not be justified. When the load was increased to 18 080 lb., the post pulled from the concrete about ¼ in., and at 22 400 lb., it pulled ½ in. After remaining for 2 hours without further movement, the load was increased to 23 840 lb., at which the post parted at the concrete line, under a load of 1 180 lb. per sq. in.

Test No. 12.—Specimen No. 12 was prepared by driving two wedges in the butt at right angles to each other. An iron band was placed around the post, 1 ft. from the butt, before the wedges were driven. The band was used to give the same results as would be obtained from the soil around the pile-head if the wedges were driven in the field, after the piles were in place. On this specimen, the band was removed before the test was started.

This test was begun on June 14, at 3:00 P. M., and was continued, with 360-lb. increments, until noon, on June 15, when the first sign of failure was noted with a load of 15 200 lb. The average diameter at the butt was 6⅜ in., and the bond area, disregarding the increase in size due to the wedges, was 240 sq. in., thus giving a unit bond strength of 63.3 lb. per sq. in.

In Test No. 10, with one wedge, the unit bond strength was 63.7 lb. These results would indicate that there would be no reason for using more than one wedge. This method of deformation would be considerably cheaper than trimming the post to a wedge shape, and also gives a higher unit strength, but there is no indication that the bond strength would be any greater than that in an anchorage without any deformation.

The driving of wedges in the pile-heads would not injure the original surface fibers, as would be the case if the methods in Tests Nos. 9 and 11 were

followed; but there would always be some "give" between the post and the wedges, and, as the load was applied, this "give" would cause the bond to break sooner than in a solid post.

Test No. 13.—In Specimen No. 13, two 1-in. pins at right angles to each other had been driven through holes in the post, 6 in. from the butt. The pins extended 1 ft. into the concrete, on four sides.

The post had a slight butt enlargement, an average diameter of 6½ in., and a bond area of 240 sq. in., after deducting for the area of the pins. The loading was started on June 16 at 8:00 A. M., and by 11:00 A. M., a load of 15 920 lb. had been applied, when failure was noted. This load was allowed to remain, but no further failure occurred. A bond strength of 66.3 lb. per sq. in. had been developed, but the failure had been so slight that the movement would not have been injurious to any structure. In fact, there was a question as to whether the slight fracture noted was really a failure due to the pulling out of the post, or whether it was due to the elongation of the wood fibers at the concrete line. The latter cause would seem to be the more plausible, because, under continued loading, no further movement was noted.

Under a load of 20 600 lb., the post parted, and the movement at the concrete line was found to be small. A bond strength of about 86 lb. per sq. in. had been developed without an injurious amount of movement.

The pin types of deformation are by far the cheapest that were tried, and the results indicate that only one pin would be necessary, if it was decided that a deformed anchorage was needed.

Description of Testing Apparatus and the Method of Testing

Fig. 2 shows the testing apparatus. The gallows-frame was designed to carry a load of 40 tons.

The method of testing was as follows: A locomotive crane would swing the specimen under the frame so that the pin could be inserted through the sling and the shackle-plates, the sling being of such length that the specimen was clear of the ground when it was released by the crane. The steel billets, each of which weighed 360 lb., were handled by a block and tackle running on a trolley. They were lowered with the least possible jar to the specimen and were racked so that a clear space was left around the post for observation and as a guard against friction of the load on the post. The post and the concrete adjacent to it were thoroughly chalked before loading was started, in order that any movement could be better detected. The increments of load were applied slowly, and as the point of failure was reached, the specimen was closely watched for any sign of such failure. As soon as the slightest line appeared, the loading was stopped for a time, in order to allow the post to pull as much as possible under that load. The points of failure were determined closely from the results of the test on Specimen No. 2 which was loaded in small increments and allowed to stand for several hours before additional load was applied.

Conclusions

Table 2 gives the results of the tests and affords an opportunity for comparing the different types of anchorage tested, for drawing conclusions as to

TABLE 2.

Test no.	Type of anchorage.	Diameter at butt, in inches.	Diameter at concrete line, in inches.	Enlargement, in inches.	Total load sustained, in pounds.	Area, in square inches of sides in bond.	Area of butt, in square inches.	Bond strength (sides), in pounds per square inch.	Bond strength, sides and bottom, in pounds per square inch.	Remarks
1	No deformation	7⅛	7	⅛	14 760	266	39.9	55.5	48.2	Pile butt soaked for 7 days before being concreted.
2	"	6¾	6⅞	⅛	21 000	252	35.8	83.3	72.9 cu. ft. dry

7	Four small track spikes driven	6⅞	6¾	⅛	16 640	257	37.1	64.7	56.6	Total movement ¼ in. at a load of 17 860 lb.
8	1-in. pin through butt one way	7 1/16	6¾	5/16	22 040	260	39.0	84.4	74.0	Total movement ⅛ in., load, 22 400 lb.
9	Trimmed to a wedge shape on two sides	7⅛	7	⅛	16 280	266	39.9	61.2	53.2	Post pulled out, load, 22 400 lb.
10	Expanded 1 in. by wedge driven into butt	6⅝	6⅝	None	15 920	250	34.5	63.7	55.9	Total movement ⅜ in., load, 20 240 lb.
11	Butt trimmed to wedge shape, four sides	6⅝	6⅜	¼	13 760	244	34.5	56.4	49.4	Post broke at top of concrete, load, 23 840 lb.
12	Butt expanded two ways by two wedges	6⅜	6⅜	None	15 200	240	31.9	63.3	55.9	Post pulled out, load, 25 280 lb.
13	Two 1-in. pins at right angles through butt	6⅝	6⅜	¼	15 920	245	34.5	66.3	57.0	Post broke at load of 20 600 lb. Movement at breaking point very slight.

the best types, and for determining a safe average bond strength to be used in designs where the factor of bond strength is necessary.

The average bond strength of nine of the tests, not including those immersed in water and those with the pins, is 66.3 lb. per sq. in., when the side area only is considered. Using the combined area of the side and bottom, the average is 58.9 lb. per sq. in. For the piles without deformed anchorage, that is, the first seven, not including the specimens that had been immersed, which are obviously low, but including the test with the spikes, the average strength is 70.5 lb. per sq. in., whereas the average of the deformed anchorages is only 65.9 lb. per sq. in. These results indicate that deformation of the pile-heads has a tendency to decrease the bond strength.

The average strength of the two plain anchorages, Tests Nos. 2 and 4, is 76.5 lb. per sq. in., whereas the average of the two highest tests of deformed heads, the two with pins, is 75.3 lb. per sq. in. Therefore, the results shown by the two best deformed types are not as good as those found with the two plain anchorages.

In conclusion, it may be stated that only the bond strength of the wood to the concrete should be considered. The deformation of the pile-heads does not warrant the added expenditure it will entail. If the substance to be anchored is of metal, a deformed anchorage will be beneficial.

The writer believes that the Sewerage Commission will not consider the use of deformed pile-heads, but will rely on the bond of the concrete to the pile. The piles to be driven will have an average butt diameter of at least 12 in. and are to be embedded to a depth of 10 in. in the concrete. The side area, in bond, is 377 sq. in., and with 12 000 lb. of uplift per pile, a bond strength of 31.9 lb. per sq. in. is necessary. This is less than the lowest result obtained in any of the tests.

The work that brought about the foregoing tests is being done for the Sewerage Commission of the City of Milwaukee under the direction of T. Chalkley Hatton, M. Am. Soc. C. E., as Chief Engineer, with James L. Ferebee, M. Am. Soc. C. E., as Principal Assistant Engineer.

Paper No. 1514

EXPERIMENTS WITH MODELS OF THE GILBOA DAM AND SPILLWAY*

By R. W. Gausmann,† and C. M. Madden,‡ Associate Members, Am. Soc. C. E.

With Discussion by Messrs. George G. Honness, B. F. Groat, Robert Fletcher, I. Gutmann, Robert F. Ewald, Thaddeus Merriman, and R. W. Gausmann and C. M. Madden.

Synopsis

This paper presents the results of experiments made with models to determine the carrying capacity of a projected spillway channel and a satisfactory section of a stepped, overfall dam. There is also a discussion of the application of the principles of homology to the models in question.

General

The Gilboa Dam, in Gilboa, Schoharie County, N. Y., forms the Schoharie Reservoir which is being constructed by the Board of Water Supply of New York City as a part of the Catskill System. A masonry section, approximately 1 324 ft. long, and an earth dike, about 1 000 ft. long, constitute the dam. The down-stream side of the masonry sections is to be formed of large steps, generally about 20 ft. high. The masonry part of the dam has a maximum height of 160 ft., and it is believed that this is the highest overfall dam of this section ever constructed. This part of the dam will be built of Cyclopean masonry, faced with native gray sandstone.

* Presented at the meeting of October 4, 1922.

Outline

This paper has been divided into three general headings:

1.—A brief history of the work done and the results obtained.

2.—A description of the experiments in the channel and on the section of the dam.

3.—A study of the differences in the results obtained with models of various scales.

History

The first model of the Gilboa Dam and Spillway was built to determine whether the channel, as designed and shown on the contract drawings under which the work is being done, was ample to carry an assumed maximum flow. The model, built on a scale of 1:50, indicated that the design was adequate, but it also showed that the steps in the overfall section did not break up the falling water as had been intended. Various modifications of the section were made, until one was found (Section 16), that seemed to meet all requirements.

Before accepting this section, it was thought advisable to experiment on a model of larger scale, as minute discrepancies made a considerable difference in the flow. The new model which consisted of only a part of the overfall section, was built on a scale of 1:20. Observation and careful measurement showed a dissimilarity in behavior in these two models, and, therefore, a larger model, on a scale of 1:8, was constructed and tested. The results of these tests proved that, as far as this section was concerned, the behavior of equivalent heads over models of different scale was not identical. This conclusion was checked further by conducting a series of experiments over flat-crested weirs built on three different scales. However, as all the results bore a certain degree of similarity, it was decided to continue the search for a suitable section, but on a model built on a scale of 1:20.

Blocks which later were modified to vanes, were placed on the upper steps to reduce the velocity, and many changes were made in the section, until a form was obtained that met all requirements. This was then reproduced on scales of 1:50 and 1:8. Measurements made over these three models still showed considerable discrepancy, but not as much as had been found in the models without vanes. This section, shown on Fig. 6, has been adopted for the Gilboa Dam to Elevation 1 020.

Experiments

Fig. 1 shows the location of the models, the details of the dam, and the controlling features. Various types of gauges were used to measure the head. Those used for all the later experiments may be seen in Fig. 2, which also shows models of Section 100 on scales of 1:50, 1:20, and 1:8, respectively, all under a proportionate head of 3 ft.

The device used to locate the outer and, in some cases, the inner edge of the jet has been called a "rectometer".* It consists essentially of two scales running in guides that are normal to each other. To determine the vacuum in various parts of the flow, a gauge was made, consisting of a U-tube of glass

with one end open and the other end connected by a rubber tube to a piece of brass tubing of small diameter, which was inserted in the water. This gauge was graduated to read directly to 0.01 lb.

Flood Discharge and Head.—To determine reasonable heads under which to conduct these experiments, the probable maximum flow of Schoharie Creek at Gilboa must be estimated. These data are given in Table 1.

A study of Table 1 made it evident that a flood of 160 cu. ft. per sec. per sq. mile might occur. Table 2, computed from the formula,* $Q = C\,L\,(H)^{\frac{3}{2}}$, in which $C = 2.64$ and $L = 1324$ ft., gives the head for various flows over the dam.

TABLE 2.

Head, in feet.	Discharge, in cubic feet per second.	Discharge, in cubic feet per second per square mile.
1	3 495	11
2	9 884	31
3	18 160	57
4	27 960	90
5	39 074	130
6	51 381	163
7	64 727	206

9	94 365	301
10	110 512	352

It was thought best to conduct experiments with heads up to 10 ft., as the maximum flood flow is indeterminate and as the vanes near the crest may cause a retardation of velocity.

* *Water Supply Paper No. 200*, U. S. Geological Survey.

Arrangement of partitions of baffle was identical for Tests A, B and C, except for Test B, a 10 in. section was removed as indicated

FIG. 1.

Spillway Channel.—A concrete model of the entire dam and spillway, on a scale of 1:50, was built and tested under a head equivalent to 6 ft. over the full-scale dam. Assuming a similarity in action between the model and its full-scale prototype and that the head selected would represent a maximum flood flow, it seemed to be evident that the channel was not only ample, but that its width and depth might be reduced.

After obtaining a satisfactory overfall section on this small scale, another model of the spillway and dam, in which the width of the channel was modified, was constructed and tested. Fig. 3 shows a head of 5 ft. over this model (Section 16), under an equivalent head of 5 ft. and flow of 40 000 sec-ft. Fig. 4 shows the depths of flow in the channel due to a head of 6 ft. The contours represent depths which were approximately constant. In general, the high and the low places along the wall and in the channel, are approximately in the same place for both a 3-ft. and a 6-ft. head. This may be due to the contraction in the channel opposite the beginning of each step. The water is the same general depth throughout the channel for the same head. Thus, on the 6-ft. head, the high water at the upper end of the channel is 13 ft. deep and, at the lower end, 14 ft., which is the greatest depth for this head. With a 3-ft. head, the maximum depth at the upper end is 5.7 ft. and at the lower end, 5.9 ft., and 6.7 ft. is the greatest depth.

As much of this work was done during freezing weather, the spray would congeal above the water line and leave a definite profile of the maximum flow. This profile is indicated by the full lines on both the retaining wall and the north wing-wall and checks closely with that obtained by measurement. Although the channel has never been tried with the accepted section of the dam, it is believed that the results will be better, as the falling jet will be closer to the dam, thus increasing the available capacity of the channel.

One might conclude from these experiments that the width of the channel could be reduced 50 ft. and that the retaining wall could be reduced from its present height of from 19 to 24 ft. to a height of 17 ft. However, no changes in the dimensions shown on the contract drawing are contemplated, largely because the maximum possible flow is indeterminate and because the action on the model will not be identical with that on its full-scale prototype.

Overfall Section.—The purpose of the experiments with the overfall section was to develop a profile in which a fairly equal proportion of the jet will impinge on the tread of each step, thus causing the jet to be broken up and its velocity reduced. At first, it was thought that this might be done by changing the location, width, and height of the steps. A considerable number of the combinations possible were built, on which experiments were made. Those experiments that gave fair results and some that gave poor results were measured.

In making these modifications, it was found that reasoning was comparatively useless, as the problem was too complicated. Minor changes in the section greatly influenced the path of the jet and often in the most unexpected manner, so that it became largely a matter of trying anything that did not seem to be too absurd.

FIG. 4.

In corroboration, the following is quoted from a discussion by the late George W. Rafter, M. Am. Soc. C. E.*:

"On this point the writer again calls attention to what seems to him ought to be understood by everybody, namely, that very slight change in the form of the weir often produces relatively important changes in the form of the coefficient curve. Reasoning from one coefficient curve to another is, therefore, without the slightest significance."

Generally speaking, the results with the better of all these sections showed that for low heads the break-up of the jet would be fairly good, but from 3 or 4 ft. up, too much water would impinge on one step, thus allowing the jet to accumulate and leap one, two, or three steps.

In nearly all the experimental sections, the tread slopes downward or drains. Many who examined the model, suggested that this step be sloped upward or, at least, made level. Models of both these types were constructed, and in that with the step sloping upward, the jet rose above the level of the step and then curved downward, missing from three to four steps. A similar effect was produced with the level step, except that the jet was not projected so far.

Section 16 and, to a slightly less degree, Section 7 gave good results on the 1:50 model, but were unsatisfactory when tested on the larger scales. After many trials, it was concluded that the desired results could not be obtained with a simple stepped section, but that some other means must be used to reduce the velocity and break up the falling sheet of water.

The early experiments along this line consisted in placing obstructions in the form of rectangular blocks, 6.0 ft. long, 3.0 ft. wide, and 4.0 ft. high, at various intervals along the tread of the first step, the long side being parallel with the edge of the step. This showed a slight improvement over sections without blocks.

Blocks were then designed, the long edge of which was at an angle of 30° with the edge of the step. The edges of these blocks were cut, so that a part was normal and the remainder parallel to the edge of the step. These blocks were tried in many arrangements. In one of these arrangements, the block was placed on the down-stream edge of the crest, and particularly good results were obtained. This arrangement, however, would raise the flow line of the reservoir higher than had been planned and, in addition, the blocks would be a constant target for floating débris, ice, etc., and a combination of circumstances might readily be imagined, in which the openings between the blocks would become clogged, thus making them valueless for retarding velocity. An isolated block or series of blocks would be difficult to hold in place.

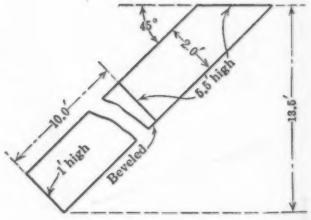

FIG. 5.

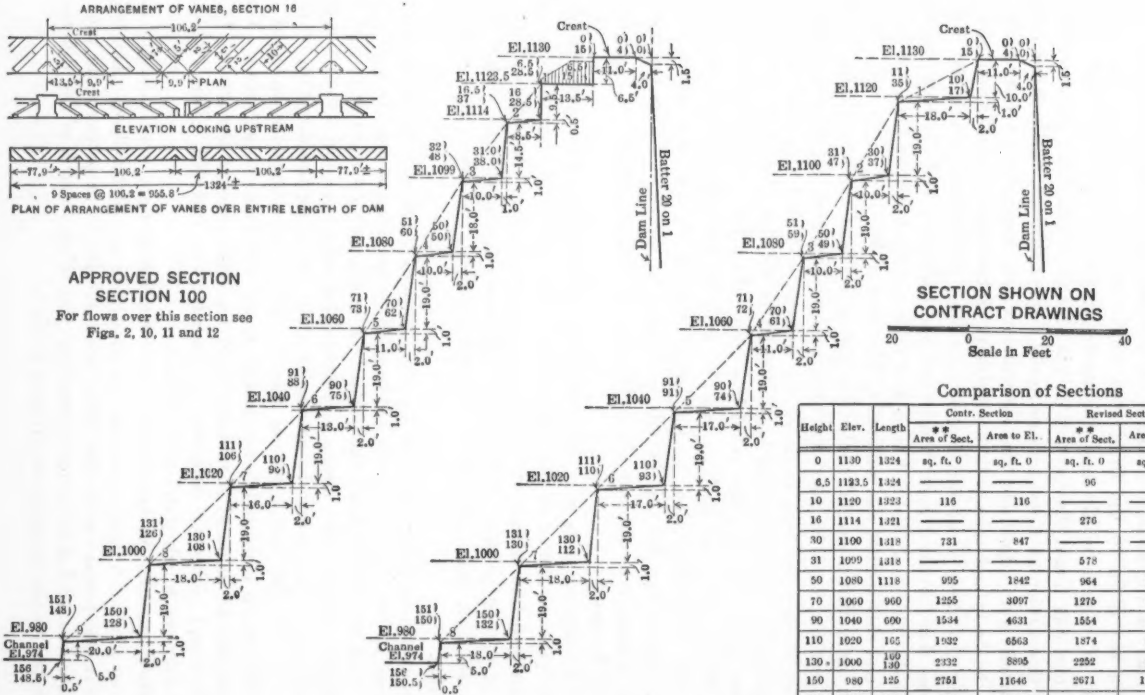
To overcome some of these troubles, the block was again placed on the first step, but was extended back to the riser, thus forming a series of vanes.

* *Transactions*, Am. Soc. C. E., Vol. XLIV (1900), p. 391.

The first experiments with these vanes were discouraging, but after many trials, a vane, shown in Fig. 5, was found, that gave better results than the blocks.



It was decided to accept the crest, first step, and vanes, and to adjust the remainder of the section to them. The model at this time consisted of a wooden top down to the third step, and concrete steps below. By using boards of various widths and thicknesses, many modifications were made, until one was found that seemed to give better results than all the others. With this section as a basis, a new model was constructed, in which the risers and treads were adjustable, and experiments were conducted by starting first with the basic and then with a maximum and minimum section and determining the three most satisfactory sections. Experiments with the three sections thus obtained were then re-run and compared, and the best one was accepted. This was modified later and improved by lowering the second step 6 in., and this section was adopted to Elevation 1020.

In order that a careful analysis might be made of the varying flows over these sections, a tabular form was prepared on which zero was used to indicate that no change has been made in the section; -1 that the tread has been dropped 1 ft., or the riser has been placed 1 ft. farther in than in the normal section; and $+1$, that the tread has been raised 1 ft., or the riser placed 1 ft. farther out. An analysis was also made of the effect of varying heads over the adjusted section, by the use of symbols to represent whether the inner edge of the flow hit heavily or lightly on the steps. This tabulation made it simpler to compare the flows over the varying heads and to analyze their differences.

The foregoing tests were conducted on a 1:20 model. As a verification, a model was constructed of the full height of the dam on a scale of 1:50, and another model, on a scale of 1:8, down to the fourth step. A detailed description of the action over these models will be given subsequently, but it may be noted here, that, although it was not identical, the discrepancy was not excessive.

In extending this section for the full length of the dam, with all the vanes pointing in one direction, water will be piled up against one end. It is thought that, with the higher flows, there will be a tendency for the water to pile up on Step 2, unless some means is provided for admitting air behind the jet at intervals. This might be accomplished by changing the direction of the vanes at intervals, as shown on Fig. 6. Other considerations have led to the decision to make only one change in the direction of the vanes. This change will be made at the west end of the dam opposite the gorge. One hundred and eighty-six different experiments were recorded. This includes flows over one hundred different sections.

Miscellaneous.—As experiments were conducted, tests were made to determine whether a partial vacuum was present in any of the flows. The only place it was found was in the whirl below the blocks or between the vanes. On the 1:8 model, a series of ten readings was taken on each of five different heads, the results of which are given in Table 3.

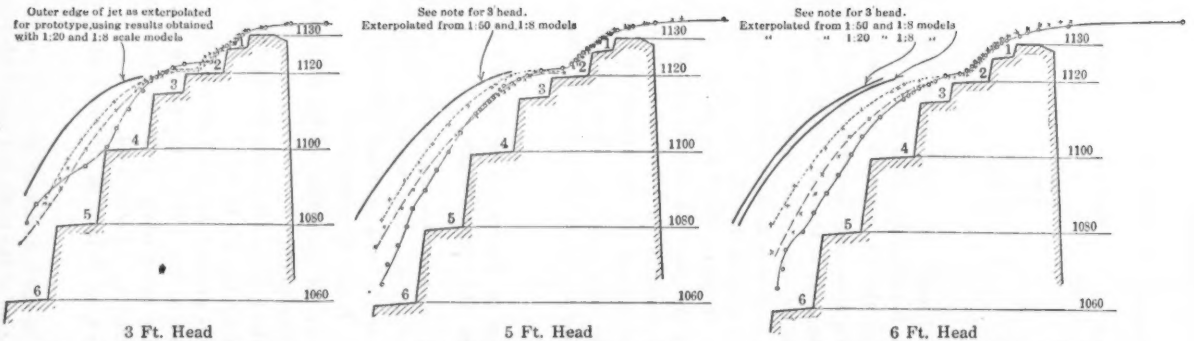
6	0.23	0.13	0.19
8.7	0.20	0.07	0.14

It seemed to be the general impression that, on the models without vanes, a negative pressure might be found under the jet from the crest to the first step where the water back of the jet was at a noticeably higher elevation than that in front of it. Numerous tests, however, showed that the entrained air was at atmospheric pressure. It is thought that the following explanation may account for this. When the water first passes over the crest, it follows down the riser. As the head is increased, the water leaves the riser and forms a jet, the section of which is a parabola. As the head is further increased, the curve is extended. Now, if both ends of the jet are sealed, an air-tight compartment is left back of the jet. As this compartment is enlarged by increases of head, there is a tendency for a partial vacuum to form back of the jet, but this is counterbalanced by the atmospheric pressure outside, forcing the water up in the compartment. Thus, as the compartment is enlarged, the water level behind the jet is raised, but the atmospheric pressure is not reduced.

Dissimilarity in Action of Proportionate Flows Over Models of Different Scales

Field Observations.—The dissimilarity, referred to previously, will now be discussed in detail. Fig. 7 shows the relativity of the outer and inner edges of jets for models of Section 16, built on three different scales and tested under heads of 3, 5, and 6 ft. It may be noted that:

1.—A similar divergence of the outer edge of the jet, due to the scale of the model, is found for all three heads.



2.—On the crest, the depth of the water is less for the 1:50 model than for the 1:20 model, and greatest for the 1:8 model.

3.—On Step 2, the depth is greatest for the 1:50 model.

4.—Between Steps 3 and 5, the outer edge of the jet, for the 1:20 model, is midway between the outer edges of the jets for the 1:8 and 1:50 models; this is particularly true for the 6-ft. head.

5.—The location of the jet, as defined by its inner edge, varies with the scale of the model.

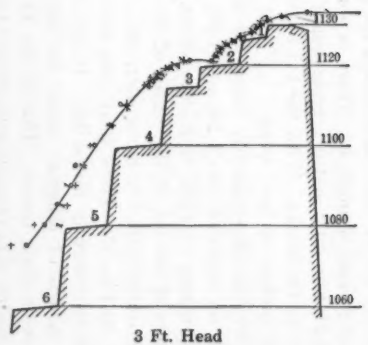
At first, the discrepancy in the behavior of the 1:50 and 1:20 models was thought to be due to the location of the baffle, but nearly identical results were obtained after moving the baffle, as shown by Fig. 1. Fig. 8 gives definite proof

3 Ft. Head

1:50 scale. The inner edge of jet hits all steps.
1:20 scale. The inner edge of jet hits steps 1 and 2, completely misses step 3; about 5% of flow hits step 4, about 20% hits step 5, entire flow hits step 6.
1:8 scale. The inner edge of jet hits steps 1 and 2, completely misses steps 3 and 4; about 2% of flow hits step 5.

5 Ft. Head

1:50 scale. The inner edge of jet hits steps 1, 2 and 6, completely misses steps 3, 4 and 5.
1:20 scale. The inner edge of jet hits steps 1 and 2, completely misses steps 3 and 4, about 10% of flow hits step 5, about 60% hits step 6.
1:8 scale. The inner edge of jet hits steps 1 and 2, completely misses steps 3, 4 and 5.



6 Ft. Head

1:50 scale. The inner edge of jet hits all steps except step 3.
1:20 scale. The inner edge of jet hits steps 1 and 2, completely misses steps 3 and 4; about 5% of flow hits step 5, 50% hits step 6, entire flow hits step 7.
1:8 scale. The inner edge of jet hits steps 1 and 2, completely misses steps 3, 4 and 5.

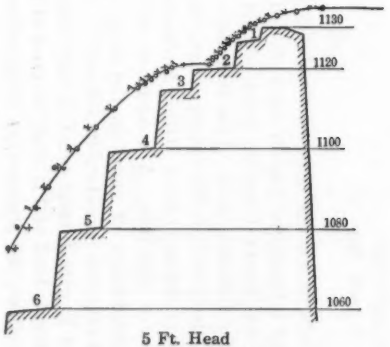
FIG. 7.

3 Ft. Head

Description



The sections shown are a 1:20 scale model of Section 16.

The difference in identical flows is presumbly due to arrangement and location of baffles built to eliminate surge.

The crosses represent points of actual measurement of Tests A and B; the circles represent the measurements of Test C.

For Tests A and B, the baffle was parallel with, and 5 ft. upstream from, crest of model.

For Test C, the baffle was located at foot of the falls, 80 ft.± upstream from, and approximately normal to, crest of model.

of the consistency of the jet under similar conditions and of the accuracy of the measurements.

Fig. 9 shows the measurements taken on jets over the 1:50, 1:20, and 1:8 models of the accepted section, with a proportionate head of 5 ft. On the 1:20 and 1:50 models, the outer edge of the jet shown was determined by holding a straight-edge level in such a position that the outer part of the outside face of the jet just touched the straight edge. This point was then projected on the board forming the end of the model. The circles in Fig. 9 represent these points. On the 1:8 model, the points were located in a similar manner, except that it was found more practical to locate the point by eye than by the use of a straight-edge. A part of the jet hit the tread of each step on all models.

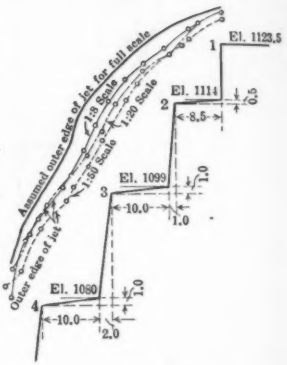

FIG. 9.

It was found by measurements in the field that the outer edge of the jet of the 1:20 model is about midway between the jets on the 1:50 and 1:8 models. From this, by interpolation, it was assumed that the outer edge of the jet may be approximately located for the full-scale dam. This assumption is checked theoretically by the fact that the force of the falling water, which projects the spray, increases as the cube of the scale ratio. Other forces, however, may materially change the location of this line. A comparison of Fig. 9 with Fig. 7 will show, that the introduction of vanes in the upper part of the section, by diminishing the velocity, has considerably reduced the dissimilarity due to scale. Figs. 10, 11, and 12 give further proof of this dissimilarity, by showing the effect of a proportionate head of 3 ft. over the crest of the accepted section on models of all three scales, the photographs being enlarged to show the models the same size.

The water passes over the vanes of the 1:50 model (Fig. 12) with no perceptible break-up. The surface of the jet is so smooth that the grain of the wood in the vanes can be readily seen through it. There is some break-up of the jet with the 1:20 model (Fig. 10), and a certain quantity of spray is cast out, as the water falls over the blocks. With the 1:8 model (Fig. 11), a large proportion of the jet is broken up into spray.

In order to test further for this dissimilarity, three flat-crested weirs, with a free overfall, were built on scales of 1:8, 1:20, and 1:50, with a proportionate length of 30 ft. Sections of these weirs are shown on Fig. 1, and the outer and inner surfaces of the jet, at the center of the weir, under heads of 3, 5, and 6 ft. as measured with the rectometer, and plotted on a proportionate scale, are shown on Fig. 13. These three jets, although following the same general line, are consistently dissimilar. It will be noted in comparing the jets over the models of different scales for any head, that there is a consistent divergence in their traces. This is due to the proportionately different effects of viscosity, skin friction, and surface tension, owing

FIG. 10.—GILBOA DAM, SCALE 1:20, PROPORTIONATE HEAD, 3 FT.

FIG. 11.—GILBOA DAM, SCALE 1:8, PROPORTIONATE HEAD, 3 FT.

FIG. 12.—GILBOA DAM, SCALE 1:50, PROPORTIONATE HEAD, 3 FT.

to the scale of the model. It will also be seen that this divergence is greatest for the 3-ft. head and least for the 6-ft. head, because the proportionately different effects of viscosity, etc., are greater at low heads.

Theory of Models.—In the Century Dictionary, the word, model, is defined as:

"A detailed pattern of a thing to be made; a representation, generally in miniature of the parts, proportions, and other details to be copied in a complete production.

"A mechanical imitation or copy of an object generally on a miniature scale, designed to show its formation; hence, an exact reproduction; a facsimile."

In the following discussion, a model will be considered to be in exact geometrical similarity to its prototype, with all linear dimensions in the same scale ratio.

The late William M. Torrance, M. Am. Soc. C. E.* took up the design of static structures from models, and pointed out that a model water tank on a scale of 1:30 was proportionately thirty times stronger than its full-scale prototype. Fig. 14 shows similar computations for a water tower, a beam, and a gravity dam, the principle being the same in all cases, namely, that the unit strength varies inversely with the scale ratio. In dynamic models, the principal causes of dissimilarity in action are: Force, velocity, viscosity, and atmospheric pressure.

B. F. Groat, M. Am. Soc. C. E.,† presents the following formula for extraneous force ratio: For the proportionality of force ratio between the model and its prototype, when the tests are conducted on the same place on the earth's surface, the ratio of the densities of the two substances equals the ratio of the cube of the linear dimensions. If the same substance is used for both model and prototype, the extraneous forces are proportional to the cube of the scale ratio.

This may be illustrated by the following numerical example: Visualize a 4-ft., solid, wooden cube, weighing 56 lb. per cu. ft., and a model of the same material on a scale of 1:2. The large block will weigh 3 584 lb. and the small block, 448 lb. If the larger block falls 20 ft., its velocity will be 35.87 ft. per sec., and the time required will be 1.12 sec. The force, $\frac{\text{velocity} \times \text{mass}}{\text{time}}$‡ = 115 820 ± ft-lb. per sec. Using the same linear scale ratio, the smaller block will fall 10 ft., and its velocity will be 25.36 ft. per sec., the time, 0.789 sec., and the force, 14 400 ± ft-lb. per sec. Thus, the ratio for the model and its prototype will be 1:8, or as the cube of the scale ratio.

If the smaller block is made of cast iron weighing 448 lb. per cu. ft., and the scale ratio remains the same, the weights will vary as 1:8, or as the cube of the scale ratio, and both cubes will weigh the same. If the smaller block falls 10 ft., its force will be the same as the larger block falling 20

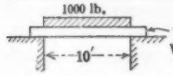
ft. Thus, if materials of different densities are used, to obtain an equal force, the scale ratio for the model and its prototype will be the cube root of the densities.

Water Tank

Water Tank

(1) Compute stress in lb. per sq. in. on lower end of post where it enters the ground



Weight of water = 10 x 10 x 5 x 62.5 =	31 250	lb.
" " tank = 0.5[(5 x 4 x 10.5) + 11^2] x 50 =	8 275	lb.
" " posts = 15 x 1 x 1 x 4 x 50	3 000	lb.
Total Weight	42 525	lb.
Weight per post	10 631.2	lb.
Weight per sq. in.	73.8	lb.

(2) Compute same data for a model built on a scale of 1:10

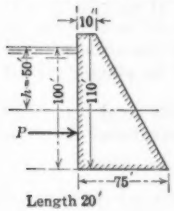
Weight of water 1 x 1 x 0.5 x 62.5	31.25	lb.
" " tank = 0.05[(0.5 x 4 x 1.05) + 1.1^2] x 50 =	8.275	lb.
" " posts = 1.5 x 0.1 x 0.1 x 4 x 50 =	3.00	lb.
Total Weight	42.525	lb.
Weight per post	10.631	lb.
Weight per sq. in.	7.38	lb.

Results

Weight varies as the cube of the scale ratio
Area " " " square " " " "
Strength " inversly as " " "
i.e. the unit strength of the model is ten times that of its prototype.

Simple Beam

Let W = weight of load and beam = 1344 lb.
L = length of span = 120 in,
b = width of beam = 10 in. d = depth of beam = 10 in,
s = stress in lb. per sq. in.



$\frac{WL}{8} = \frac{sbd^2}{6}$ s = 121 lb.

For model scale 1 to 10 W = 1.34 lb. L = 12 in. b = 1 in.

$\frac{WL}{8} = \frac{sbd^2}{6}$ d = 1 in. s = 12.1 lb.

Results

Weight varies as the cube of the scale ratio
Area " " " square " " " "
Strength " inversly as " " "

Weight of Masonry 125 lb. per cu. ft.

Dam (Stability)

Full Scale	Model
$P = ahw$ = 6 250 000 lb.	$P = ahw$ = 6 250 lb.
Weight of dam = 11 687 500 lb.	Weight of dam = 11 687.5 lb.

Therefore stability against overturning is the same in the model and prototype

Dam (Pressure on Base)

$$\text{Unit Press} = \frac{P + \text{Weight of dam}}{\text{Area of base}} = \text{11 958 lb. for full scale and}$$

1 195.8 lb. for 1:10 model, thus the unit pressure is inversly proportional to the scale ratio

FIG. 14.

Mr. Groat* gives a theoretical discussion on the proportionality of the velocity in a model and its prototype. Briefly, it is as follows:

By the Chezy formula for the flow in channels or rivers, $v = c\sqrt{rs}$; let this equation stand for the flow in the model, and let $V = C\sqrt{RS}$ be the equation for flow in the full-size prototype. Then, $\frac{v}{V} = \frac{c\sqrt{rs}}{C\sqrt{RS}}$ will show the relation between the two flows. If both the model and its surfaces are

* *Transactions*, Am. Soc. C. E., Vol. LXXXII (1918), p. 1173.

geometrically similar to the prototype, then $\frac{c}{C} = 1$ and $\frac{s}{S} = 1$. Squaring and eliminating, $\frac{v^2}{V^2} = \frac{r}{R}$; therefore, $\frac{v}{V} = \frac{\sqrt{r}}{\sqrt{R}}$, showing that the "velocities should be proportional to the square roots of the hydraulic radii, and, therefore, to the square roots of any homologous linear dimension", or to the square root of the scale ratio. It can be shown that this will apply equally well to a weir. Thus, if a model of a weir or channel is geometrically and mechanically similar to its prototype, the velocity will vary as the square root of the scale ratio. Generally speaking, it will be found difficult in the construction of practical weirs to make the ratio of the two coefficients of roughness equal unity and, consequently, $\frac{c}{C}$ will not exactly equal unity.

The velocity of the wind will vary in the same manner as other velocities, that is, as the square root of the scale ratio. A 5-mile breeze on the model, on a scale of 1:50, will be equivalent to a 35-mile wind on the full-scale prototype.

Mr. Groat* states: "This shows that cases of pure stream-line flow cannot be reproduced in models unless the sizes of the models are properly determined by Equation (19)". This equation is, $L^{\frac{3}{2}} = N(G)^{-\frac{1}{2}}$, in which L equals the scale ratio, N the ratio of the kinematical coefficients of viscosity corresponding to the coefficients of viscosity of different fluids used in the model and the prototype, and G equals the gravity ratio.

"As examples of the uses of Equation (19), when $G = 1$, it may be shown: (*a*) that a model air propeller in mercury at 20° cent. should be one-twenty-fifth full size for the prototype in air at 15° cent.; (*b*) that the scale ratio of a model water-wheel tested in mercury at 20° cent., should be about 0.22 for the prototype in water at 15° cent. * * *"

"* * *. With $G = 1$, Equation (19) shows that the model requires a different fluid from that for the prototype when both observations are made at the same place."

Thus, to give the same results as its prototype, an overfall dam should have its model tested with some liquid other than water.

Under ordinary conditions of testing, the atmospheric pressure is the same for both the model and its prototype; thus, in the prototype the atmosphere will support a column of water 33.9 ft. high. As the atmospheric pressure remains practically a constant, it will support the same height of water in a model regardless of the scale. Thus, in a model on a scale of 1:50, the atmosphere would apparently support a column of water 1 695 ft. high. Unless some means are taken to reduce this pressure, proportionately to the scale of the model, in hydraulic flows in which there is a partial vacuum, or negative pressure, the action of the model will differ from that of its prototype.

Application of the Theory of Models to the Models of the Gilboa Dam.—Probably the principal cause for the dissimilarity below the crest in models

* *Transactions*, Am. Soc. C. E., Vol. LXXXII (1918), pp. 1186–1187.

of various scales, is the variation in force due to the scale of the model. It has already been shown that this varies as the cube of the scale ratio. Thus, the force exerted by any part of the jet falling on the 1:8 scale model is 2.5^3, or 15.6 times greater than the force exerted by the homologous part of the jet falling on the 1:20 model, or $6.25^3 = 244.1$ times greater than on the 1:50 model. This force is largely expended in breaking up the jet and in causing the particles of the jet to be projected farther.

It is believed that this explains the difference in the action over the vanes, as shown in Figs. 10, 11, and 12. A study of these photographs will show that, in the 1:50 model (Fig. 12), the surface of the jet passing over the vane and first step is nearly smooth. The impact is so slight, as the water passes over the edge of the vane and falls on the tread of the first step, that there is scarcely any noticeable break-up.

On the 1:20 scale (Fig. 10), where the fall of the water exerts a force 15.6 times greater than on the 1:50 model, a considerable break-up is noticeable where the water falls over the vanes and crest and impinges on the first step.

On the 1:8 scale (Fig. 11), the force exerted by the falling water is 15.6 times greater than in the 1:20 model, and 244.1 times greater than in the 1:50 model. In this case, there is a marked break-up in the jet as it flows over the first step. In no place is the smoothness so noticeable as in the 1:50 model, or even in the 1:20 model.

Some idea of the break-up which will occur in the full-scale prototype, may be obtained by first comparing the 1:50 and 1:8 models, in which the force ratio is 1:244.1, and then attempting to visualize the full-scale model in which the force will be 512 times the 1:8, or 125 000 times the 1:50, model.

The dissimilarity in models below Step 1 is probably best shown on Fig. 9. On this diagram, the outer edge of the jet has been plotted for a proportionate head of 5 ft. It will be noted that, generally speaking, the difference in force has had the effect of placing the outer edge of the jet a little farther away from the weir as the scale increases. The experiments seem to show, however, that, in this model, the center of the jet remains in approximately the same location for all heads and that the break-up simply increased the area of the jet. In this connection, it will be noted that the area of the jet flowing over Step 1 is larger in the 1:8 scale than in the 1:20 scale. (See Fig. 9.)

It must be noted, however, that below Step 4 this is only conjecture, as the 1:8 model did not extend below that point. It is thought that the outer edge of the jet on the full-scale model will be proportionately farther out, or, in other words, it may be exterpolated from the location of the jets on the three models. This is assumed by noting that the general location of the outer edge of the jet of the 1:20 model is midway between the 1:8 and 1:50 models.

As a further check on the theory that the dissimilarity in models of stepped overfall dams is caused partly by variation in force exercised by the falling water, due to the scale of the model, reference is made to the studies of the flow over Section 16.

Between Steps 3 and 5, the location of the outer edge of the jet varies with the scale of the model, its distance from the dam being greatest for the 1:8 scale. Probably the principal cause for this is that the energy of the jet, as it impinges on Step 2, is greatest for the 1:8 model, thus causing the jet below that point to be projected farther than in the other models.

From measurements on flows over the flat-crested weirs, taken in the field, it was possible to determine with considerable accuracy the area of the jet on the down-stream edge of the crest, and with this area and the computed quantity, the velocity was calculated. Table 4 shows the computed velocities, in comparison with the theoretically proportionate velocities. The theoretically proportionate velocities were determined by assuming the velocity for one scale as standard, and computing the other by multiplying or dividing by the square root of the scale ratio.

TABLE 4.

Model.	Computed velocity, in feet per second, assumed as actual velocity.	Assuming 1:8 model as standard.	Assuming 1:20 model as standard.	Assuming 1:50 model as standard.
1:8	4.99	.....	5.02	5.11
1:20	3.18	3.16	.....	3.23
1:50	2.045	2.00	2 01	.....

It will be noted, that the proportionate velocities shown in Table 4, do not differ greatly from the velocity assumed as correct, but they do differ sufficiently to change the curve of the jet so that it will not check the curve measured in the field.

As already stated, therefore, the writers conclude that flows over models of broad-crested weirs, although giving results that approximate closely those over the prototype, do not show an identical similarity, owing to the fact that the coefficient of flow over a broad-crested weir is not always proportional to the ratio of head and width of crest, due largely to the disproportionate effect of skin friction and viscosity.

By computation, it can be shown that by changing the geometrical similarity to a slight degree, that is, by using a corrected head, flows may be obtained which are identically similar for all models. Thus, if instead of a 6-ft. proportionate head (0.75-ft. head (actual scale), on the 1:8 model), a head of 0.69 ft., actual scale, is substituted, a quantity is obtained that corresponds with the quantity computed for the full-scale model. For the 1:20 scale, the head will be 0.255 ft. instead of 0.30 ft. (both actual scales), and for the 1:50 scale; 0.10 ft. instead of 0.12 ft. These results have never been checked in the field, but are thought to be fairly accurate as the retardation of velocity, due to a broad crest, increases with the scale of the model.

Owing largely to the effect of skin friction and viscosity, the jets over model flat-crested weirs do not exactly check each other. A description of these weirs and the tests on them has already been given. It remains to prove theoretically why these jets do not follow the same line when plotted on a proportionate scale (Fig. 13). If these jets followed the same line, the

velocities would be in proportion to the square root of the scale ratio, and the coefficient, $\frac{c}{C}$, would equal unity. (See page 297.)

The following paragraph is quoted from a paper by Richard R. Lyman, Assoc. M. Am. Soc. C. E., entitled, "Measurement of the Flow of Streams by Approved Forms of Weirs with New Formulas and Diagrams,"* in which a graph is shown giving heads and corresponding discharges over broad-crested weirs:

"It should be noted that, for comparatively low heads, all these broad-crested weirs give practically the same result for the same head. At a particular head or point, however, for each width of crest, the quantity of discharge begins suddenly to increase much faster, in proportion to the head, than it has done before, and the line representing its discharge breaks away from *AA* and extends across the diagram [Plate XXIV] in a slanting direction to the line, *BB*, which represents the discharge over weirs with sharp crests."

A study of this statement and the graph will lead one to believe that the models of broad-crested weirs, on different scales, will not check. If they were identically similar, the lines representing width of crest would be straight and not broken. If the action of a model is precisely similar to its prototype, then, in the formula for discharge over broad-crested weirs,

$$Q = C\ 3.33\ L\ (H)^{\frac{3}{2}},$$

C, which depends on width and head, should be a constant for the model and its prototype, regardless of the scale of the model, as in the model the ratio of width and head would be the same as in the prototype. A table† compiled by Gardner S. Williams, M. Am. Soc. C. E., from the Cornell experiments on flow of water over weirs, will prove that this is not true. As an example: With the head of 2 ft., and a width of crest of 1.65 ft., the coefficient is 0.925. Multiplying both head and width of crest by 2, the coefficient is 0.807.

As a further check, the flow over a weir 30 ft. long, 6 ft. wide on the crest, with a head of 6 ft., with end contractions, was computed, using the formula,

$$Q = 2.64\ (L - 0.2\ H)\ H^{\frac{3}{2}};‡$$

for the models, the following formula was used,

$$Q = 3.33\ (L - 0.2\ H)\ H^{\frac{3}{2}},$$

with the exception that for the 1:8 model a correction was applied for broad crest. These computed flows were then compared with proportionate flows obtained by the formula,

$$\frac{Q}{q} = \frac{A\sqrt{2\ G\ H}}{a\sqrt{2\ g\ h}}.$$

The results of these computations are shown in Table 5.

* *Transactions*, Am. Soc. C. E., Vol. LXXVII (1914), p. 1199, and Plate XXIV, p. 1205
† "Waterworks Handbook", by Messrs. Flinn, Weston, and Bogert, Table 196, p. 601.
‡ Merriman's "Hydraulics", p. 161.

TABLE 5.

Model.	Computed flow, in second-feet.	Comparison with full scale, second-feet.	Comparison with 1:8 scale, second-feet.	Comparison with 1:20 scale, second-feet.
Full scale.....	1117.7	.....	.....	.....
1:8.....	7.018	6.16	.....	.....
1:20.....	0.7864	0.625	0.7107	.....
1:50.....	0.081	6.059	0.064	0.073

This proves that, in models of broad-crested weirs, as $\frac{c}{C}$ does not equal unity, mechanical and geometrical similarity cannot be obtained simultaneously, owing, in all probability, to the proportionately different effect of skin friction and viscosity. In determining the proper quantity for this tabulation, it seems best to use that quantity, the computed jet of which plotted nearest to the actual jet as measured in the field.

For each flow, the quantities were computed by each of the following formulas: Bazin, Fteley and Stearns, Francis, and U. S. Geological Survey. Using the velocity derived from these formulas, paths of the jet were plotted by applying the jet formula,

$$x = vt,\ y = \frac{1}{2}\ gt^2,$$

and compared with the curves that had been determined in the field by locating the inner edge of the jet. The accepted quantity for each flow was that one the jet of which was nearest to the jet located in the field. Similar computation sheets were made for the 1:20 and 1:50 models.

For comparison, the theoretical parabola, derived from the formula:

$$x = \frac{2}{3}\sqrt{2\,g\,h}\ t^*,\ y = \frac{9}{16}\frac{x^2}{h},$$

was plotted. This line was considerably under the inner edge of the jet as measured, and, therefore, does not represent as great a velocity.

The main causes, therefore, for the dissimilarity in action over these models are: Difference in force; difference in coefficients of flow over a broad-crested weir, due to skin friction and viscosity; and difference due to atmospheric pressure, when parts of the flow are not open to free circulation of air.

Effect of Dissimilarity of Models on Experiments with Flow in Channel.— In the final experiments with the flow in the channel, Section 16 of the dam, on the 1:50 scale, was used. No experiments were made with models of any other scale, nor have experiments been made using the accepted section (Section 100) of the dam. It is thought that the revised section will tend to bring the water to the floor of the channel with a lower velocity than Section 16. However, the force exerted by the falling sheet of water will be 125 000 times greater than that in a model on the scale of 1:50. With the present limited knowledge, it would be inadvisable to predict just what the action in the channel will be.

* Encyclopædia Britannica, Vol. 14, p. 51.

General Conclusions

From observations, measurements made in the field, careful study of photographs, and a study of the theory of models, the writers conclude:

1.—That the flow over a large scale dam will be similar to a certain degree, but not identical, with the flow over its models.

2.—That, as Mr. Groat has pointed out, it may be possible to build a diminutive structure, not necessarily a model in the true sense of the word, which "must reproduce, even in detail, the performances of their prototypes", but that, in many cases, the practical difficulties encountered may make the construction and test of these models impractical. For instance, in order to obtain a proportionate test for the force of the falling water on the steps of the Gilboa Dam, it would be necessary to build a model on a scale of 1:2.38 and test with mercury at 60° Fahr.

3.—That, with a full recognition of the fact that there is dissimilarity, the model, if built on a large enough scale, still remains the most efficient method of determining the most satisfactory section for an overfall dam.

DISCUSSION

GEORGE G. HONNESS,* M. AM. SOC. C. E. (by letter).—The authors briefly state that 186 different experiments were recorded, which include flows over 100 different sections. These experiments were started in the early summer of 1919, and were continued until weather conditions in the early winter caused the work to be stopped before conclusions could be reached. A complete reconstruction of the control works and parts of the model was required in the spring of 1920 before experiments could be resumed, and then the experiments were continued until the early fall of 1920. This brief statement is not, therefore, a fair measure of the faithful, painstaking, and ingenious work done by the authors, for which they are to be commended.

As stated in the paper, the original purpose of the construction of the model was to determine the sufficiency of the spillway channel, as it was thought by some that it was more than ample, and that a considerable saving would result by a reduction in size.

The behavior of the model on a scale of 1 : 50, with a maximum flow equivalent to a 6-ft. head over the full-scale dam, indicated that a reduction of both width and depth was permissible. Experiments were then made with a width of channel reduced by 50 ft., with a head equivalent to 6 ft. on the full-scale dam, and the results are shown in Fig. 4. This shows that the reduced channel, with assumed flood flows, would probably be ample.

The flood flow of Schoharie Creek, at Gilboa, in 1869, was the highest in the memory of the then oldest inhabitant. It seems fair, therefore, to assume that the flood of 1869 was the highest in more than 100 years. A fair determination of the quantity of that flood at Gilboa was 44 100 cu. ft. per sec., or 140 cu. ft. per sec. per sq. mile, from 314 sq. miles. As stated, the channel of reduced size was shown to be ample for a flood of 51 381 cu. ft. per sec., or 163 cu. ft. per sec. per sq. mile. Notwithstanding, the channel is to be constructed as originally planned, for the reasons stated by the authors.

A more important fact than the capacity of the channel was determined by the initial experiments. With a section as originally designed, having steps of unusual height and width of tread for an overfall section, the flow passed over the crest, down the first riser, over the tread, and then the sheet of water missed the next three or four steps, falling as much as 80 ft. Hence, the necessity of continued experiments until an overfall section could be selected, which would lead to the falling sheet impinging on each successive step and thus dissipate the energy of the falling water. This was finally accomplished by placing deflecting vanes on the tread of the upper step and modifying the height and width of the other steps.

The writer concurs in the authors' conclusion, that notwithstanding the fact that the behavior of models will not be exactly similar to their prototypes, the model remains the best means of determining the design of many hydraulic structures. This conclusion is based on experience with models used to

* Dept. Engr., Board of Water Supply, New York City, Grand Gorge, N. Y.

determine the probable behavior of full-scale structures in the following instances.

Boonton Dam, Boonton, N. J.—The overfall section of this dam was located on the northerly side of the valley, so that the maximum height was not in excess of 70 ft. This required the spillway channel to make an acute angle with the axis of the dam, in order to lead the waste water to the old stream bed. The overflow from the northerly one-third of the waste weir is caught on a steep, sloped channel the maximum grade of which is parallel to the axis of the dam. The water, flowing over the steep slope, has its velocity accelerated, and this deflects the water passing through the southerly two-thirds so that it follows the axis of the spillway channel. A model was constructed to scale, and the plans were perfected after studying the action of the water passing over the model. As constructed, the channel has served its purpose, and the result is substantially the same as that obtained with the model.

During construction, the channel was advanced so that it could be used during the winter season to care for water passing over the overflow section which, as the end of the working season approached, was in such a condition that a concentrated flow over a small section of its length would pass into the channel. A model was constructed to comply with conditions as they existed, and flows over it showed that the side of the channel would be overtopped and serious damage likely to result. A modification which increased the length of the temporary overflow section several times was tried, and the contractor was required to advance the work sufficiently to bring about the conditions desired. Overflows during the winter and the following spring did no damage.

Cross River Dam, Katonah, N. Y.—Slight modifications of the waste weir and spillway channel of this dam were determined from experiments with a model section.

Ashokan Reservoir Waste Weir, Ashokan, N. Y.—The spillway channel changes the direction of flow so that it makes a right angle with the line of the waste weir. The north retaining wall contained a re-entrant angle which deflected a part of the flow, so that it impeded the flow of that part of the water moving parallel to the waste weir section. A discharge due to a head of slightly more than 1 ft. on the crest of the weir, made it apparent that modifications were necessary to meet conditions of larger flows which were to be anticipated. A model on a scale of 1 : 50 was constructed, and from its operation it was decided to remove the re-entrant angle and construct a guide-wall in the center of the channel at the right-angle bend in its alignment. No overflow has occurred since this work has been done, but it is predicted that the channel will perform its purpose more efficiently than as originally designed.

B. F. Groat,* M. Am. Soc. C. E. (by letter).—In reading the authors' instructive paper, the writer has noted that the overfall did not correspond exactly with their expectations. The question may well be asked—should it? Even if model theory was developed sufficiently to be closely applicable, no one need expect such close agreement that errors will not become apparent. This

* Cons. Engr., Philadelphia, Pa.

is true of all theories as regards exact application. In particular, the writer is of the opinion that an overfall is very sensitive to small errors, such as might occur in the measurement of the head on the crest of a model weir.

One element of correct hydraulic model construction which is difficult to create when the prototype does not exist, is a correct introduction of water to the model with corresponding correct configuration of discharge. If these two conditions are not established, an exact reproduction of performance need not be expected. In the case of the writer's model of a reach of the St. Lawrence River, the prototype actually existed, yet, owing to the roughness of the field methods used, errors of some magnitude were observed, not only in the flow within the model, but also in the attempted reproductions of entrance and exit conditions. Had these conditions been minutely adjusted, there is little doubt that a more precise homology would have been presented.

To be even partly true, the statement that the strength of model structures "varies inversely as the scale ratio", must be qualified by the word, "geometrical". When the extended meaning of the word, "model", is used, referring now to combined geometrical and mechanical similarity, no such restricted statement can be applied. In short, the moment the conditions of mechanical similarity are superposed on the conditions of geometrical similarity, the theorem of the statement becomes a "cull". The word, "model", must have an extended meaning or progress in research is at an end as regards models.

In the application of rigorous theory, the construction and testing of a model becomes a large problem. Is a valuable method of solution, however, to be dropped because it is large and troublesome? The chances will be that it is not as large and troublesome as the problem to be solved. The expenditure of time and trouble will be justified by the exactness of the results obtained. To make a model structure, for example, one may increase gravity effects by additional density, by loading, by the use of materials of correspondingly varied elastic properties and strength, by centrifugal forces produced by the rotation of the model as a whole, by measuring internal stresses in a model member instead of testing to destruction, etc. Some genius will arise to synthesize materials and fluids capable of being handled with facility in the construction and testing of models. A special study of this kind should be made.

ROBERT FLETCHER,* M. AM. SOC. C. E. (by letter).—This paper supplies in great detail the actual results looked for by B. F. Groat, M. Am. Soc. C. E., in his paper on "Ice Diversion, Hydraulic Models and Hydraulic Similarity",† which the writer discussed.‡

All readers familiar with the principles involved must be impressed by the great value of these remarkable demonstrations of what may be learned by the intelligent use of models. In the discussion referred to, the writer objected to what seemed to be too positive and all-inclusive claims for the validity of model studies, and probably over-emphasized the objections without expressing due recognition of the value of such studies when results are rightly interpreted.

† *Transactions*, Am. Soc. C. E., Vol. LXXXII (1918), p. 1168.
‡ *Loc. cit.*, pp. 1156–1162.

The thanks of the Profession are due to Mr. Groat for his very complete exposition of the theory of hydraulic models. It removes some points of haziness, which the writer confesses existed in his own mind. The interesting experiments with models of the Gilboa Dam show how much may be learned practically by the cut-and-try method.

The writer thinks, however, that the main point and intent of his criticism is justified, in all ordinary cases where experimenters have only limited means at their command and are likely to place too much confidence in results which are not conclusive. The final conclusions of the authors from the application of the formulas to the latest experiments are:

First.—A similarity to a certain degree, but not identity, in flow over the actual dam and the model.

Second.—It may be possible to build a model not necessarily a model in the true sense of the word, which "must reproduce, even in detail, the performances of their prototypes;" but, for the Gilboa Dam, the scale would have to be as 1:2.38, and the liquid must be mercury at 60° Fahr.

Third.—With due recognition of the points of dissimilarity, the model, on a sufficient scale, is the most efficient means of preliminary study of such a case as that of the Gilboa Dam.

No one would presume to dissent from the last conclusion in view of the practical demonstrations made by Mr. Groat and the authors. The second conclusion, however, is an admission of practical impossibility.

If the reason for the difficulties in adjusting the theoretical demonstration to practical conditions is considered, it is noted that it involves inclusion of mass ratio, force ratio, centrifugal reactions (in hydraulics), proportionality of heads and depths, skin frictions, wind friction, movement and transportation of detritus in river hydraulics, viscosity, duration of time observations, and factors of safety. Although all these influences are given mathematical expression in the formulas, there are certain coefficients of uncertain value involved, which forbid confidence when an attempt is made to predict what may happen when an extraordinary flood is pouring over a dam, or provision is to be made for a jam of ice or logs, or excessive wave action is to be resisted by a sea-wall, or the impact due to reaction from back-water is to be resisted at the toe of a dam, or in other cases where the forces of Nature are likely to get beyond control. As Mark Twain said, "we are harassed by doubts".

The elaborate German experiments, quoted from the work on river hydraulics* by J. L. Van Ornum, M. Am. Soc. C. E., in the writer's discussion previously mentioned, resulted in great uncertainties and lack of very definite conclusions, although useful in some respects. The artifice of using bags of shot and pieces of slate for groins and bank protection in the models surely did not realize conformity in mass to materials available for actual constructions on the river.

To be consistent, one must believe that it would be possible to make a model of Niagara Falls, which would reproduce on a reduced scale proportional effects to the erosion and destruction wrought by the mighty cataract, or that

* "The Regulation of Rivers," pp. 163–172.

officers of the U. S. Ordnance Department could make a model of a 16-in. gun and invent an explosive of detonating effect proportional in the scale ratio to the effect of the actual high explosive used in warfare, and thus predict the safety of the large gun.

In discussing the application of the formulas expressing "the inexorable laws of mechanics" to the model of the Meigs elevated railway, Mr. Groat shows, perhaps conclusively, that, after a certain number of "ifs" had been duly satisfied, "the factors of safety in model and prototype would have been equal", and then adds: "It is not doubted that it would be something of an undertaking to construct and test such a model, but the fact which we have proved is that it can be done." Again, the verdict is, not really practicable because of inherent limitations.

Acknowledging the great value of all the experiments described, which have specific ends in view, the writer would disclaim any intention, both now and heretofore, to under-estimate the value of the judicious use of models. The caution is against the misuse of them, especially by inexperienced experimenters.

I. GUTMANN,* ASSOC. M. AM. SOC. C. E. (by letter).—In 1919, the writer was instructed by G. A. M. Elliott, M. Am. Soc. C. E., Chief Engineer of the Spring Valley Water Company, of San Francisco, Calif., to prepare a tentative design for a spillway for the Calaveras Dam. The spillway was to take care of a drop of about 200 ft.

An extensive preliminary study, covering more than seventy reservoir spillways in all parts of the world, was made in connection with this design. Special attention was given to stepped spillways or cascades, that is, the type used on the Gilboa Dam.

Stepped spillways and wasteways have been used in European† and American‡ practice for many years, yet the principles for their design have not been formulated, and the writer had to state that there was no reliable formula for the flow of water over cascades. The absence of water-cushions and the consequent progressive increase in velocity of approach preclude a satisfactory analysis. At low heads, each step may be treated as a drop, with no raised crest, and the formula, $Q = 4.75\ L\ H^{\frac{3}{2}}$, may be used. German engineers prefer the Kutter formula. At high heads, with the water being projected farther horizontally and not all the nappe striking the next step, the problem will become more complex and the formulas preposterous.

The writer has been especially interested in this valuable paper which presents the results of the authors' experiments to determine the conditions of flow over the stepped overfall dam at Gilboa, N. Y., by means of a set of models.

Experiments with models could not be expected to furnish very accurate results in this particular case which is essentially dynamic and involves so

complex a phenomenon as the successive impingements of a sheet of water of varying head on masonry steps of varying width and height. Considering the 1 : 8 model (Fig. 7), as a prototype, and the 1 : 20 and 1 : 50 models as its 1 : 2½ and 1 : 6¼ reductions, one will conclude that it will require unusual intuition to exterpolate the curve of flow over the prototype from observations on the models, especially in the case of ordinary heads, namely, less than 4 ft. or more.

More consistent and, therefore, more serviceable results were obtained with the models of the "approved Section 100" (Fig. 9). It may be said, perhaps, that Section 100 was approved because the models of it gave more consistent results, these results being due probably to the greater uniformity of its profile. The rises of the steps in Section 100 are consistently greater than their treads, whereas, in the experimental sections, the rises are smaller than their treads, in the uppermost three steps and greater in the steps below the third, therefore, in Step 2, the ratio of rise to tread is 1 : 1½, and in Steps 5 and 6, the ratio is 2 : 1.

Most of the "discrepancy" or "dissimilarity" with the experimental models probably originated on Step 2, the tread of which was long enough to deflect and to project the falling nappe in a horizontal direction, whereas the profile of the model, near that point, takes a vertical deflection downward with reference to its original trend. The flow curve diverges from the profile, and the dissimilarity between the models, which becomes prominent below this point, is probably due chiefly to the mass effect of their respective volumes of water which had impinged on and were deflected by the tread of Step 2.

In the "approved Section 100", the horizontal deflection of the nappe taking place on Step 2 of the experimental sections, was suppressed by shortening the tread of Step 2 and by a general steepening of the upper part of the profile of the dam. This made the profile more uniform in respect to rise and tread proportions, the structure becoming geometrically simpler and the results more consistent.

Better results were obtained by the authors in their tests of models of broad-crested weirs, the obvious reason being the greater simplicity of the structures and the absence of the complex impingement factor. In connection with these tests, the authors made the interesting observation that kinetic dissimilarity may be eliminated "by changing the geometrical similarity to a slight degree, that is, by using a corrected head, flows may be obtained which are identically similar for all models", irrespective of their scale. The corrections computed by them for the three models used seem to be consistent when properly plotted against the scales of the three models. Curves based on such observations might supply a very useful link for the correlation of observations on models with what may be expected to occur on full-scale structures.

In general, the study tends to show that the method of models, if rationally and cautiously used, can be reasonably depended on even in quantitative studies of proposed broad-crested weirs and other hydraulic structures not unduly complicated.

The authors deserve great credit for their thorough investigation and their valuable contribution to hydraulic literature.

ROBERT F. EWALD,* ASSOC. M. AM. SOC. C. E. (by letter).—There is much to commend and little to criticize with respect to the methods used in and the conclusions obtained from the admirable series of experiments made on models of the stepped profile type of dam. The general type of dam to be used apparently had been decided on before the experiments were undertaken, and as no mention is made in the paper of tests on smooth-faced ogee spillway dams, it appears that such a dam was not seriously considered owing, no doubt, to the apparent difficulty of properly absorbing the high velocities of the water at the toes of dams of that type. In the light of knowledge gained during the past ten years, the apparent difficulty has disappeared, and as there are certain inherent serious disadvantages in the stepped type of overfall dam, there are strong reasons for believing that a series of experiments as ably conducted should have been carried out to determine physically the feasibility of a smooth-faced ogee dam before the stepped profile was adopted.

The writer has never been enthusiastic over the stepped type of spillway dam, notwithstanding its occasional use in the northeastern part of the United States. It is not easy for him to get away from the idea that the absorption of hundreds of thousands and possibly millions of horse-power of energy by "pounding it out" on the dam itself cannot be done without immediate serious destructive action on the dam and within areas where such action is least desirable and most dangerous.

Cyclopean and coursed masonry and even concrete deteriorate considerably in time in so far as freedom from cracks is concerned. Wide variations in temperatures and to some degree in stresses, due to loads, ultimately develop cracks, possibly very minute but, nevertheless, present and extending to considerable depths. This tendency to crack is considerably facilitated by the greater exposure and angles introduced by the stepped construction and by the entrance of water under direct impact, which takes place on every step. It can be only a relatively short time before the corners of the steps are broken away, due to weathering and impact. After this has happened, it is highly probable that the exceptional flood will come and the steps, now no longer of sufficient width to function properly, will then become a source of positive danger. In the same manner as discussed in the experiments, where the steps were not made sufficiently wide, some of the water with its velocity unbroken will reach the lower parts of the face of the dam with sufficient energy to develop erosive action which the lower steps cannot withstand for any appreciable length of time. The result will be rapid destruction of the steps and serious attrition of the main body of the dam near its base where the stresses are greatest and where adequate repair will be most difficult if not impossible.

The great rapidity with which raveling action proceeds where water is flowing at high velocities over or directed against checked and cracked sur-

* Asst. Engr., Aluminum Co. of America, Pittsburgh, Pa.

faces, especially where these surfaces are irregular, is familiar to many engineers. The writer has in mind as a particular case the tremendously destructive action of water flowing at a velocity of about 45 ft. per sec. in a spillway channel newly excavated in a very hard rhyolite formation. The surface as left by the contractor was rough and broken, but as blasting had been very light in order to prevent as far as practicable the breaking of the rock left in place, it is difficult to believe that fracture at depths greater than 10 ft. could have been more than what one would term "hair cracks", yet in the course of a few days during the first big flood discharging through the channel, holes 15 ft. or more in depth were scooped out of the ledges in place and blocks of rock many tons in weight carried down the channel. The average slope of the channel was about 30 ft. vertical in 100 ft. horizontal, and the maximum depth of water in the channel at the beginning of the flood was about 7 ft.

Water may be allowed to flow over smooth concrete at very high velocities for a long time without appreciable wear, but where slight irregularities develop, erosive action appears and increases with great rapidity. The initial irregularities need be very slight to start the trouble. The writer has recently inspected some photographs of the down-stream toe of an ogee spillway dam, over which water has been flowing with velocities of more than 100 ft. per sec., in which there is evidence that wear is beginning at the horizontal joints marking different pourings of concrete, and it is safe to say that the erosion at these points will develop rapidly. These bonding joints were made with the greatest care and the lines of division must have been microscopic, nevertheless, they appear to be sufficient to give the water its initial "grip". On the adjacent areas, originally smooth and unbroken, the wear is very slight.

The statement no doubt will be made that the steps can be repaired and renewed from time to time, but this involves a heavy maintenance charge and if not done may ultimately result in trouble, as it is not certain that those in charge of the dam in the future will appreciate the necessity of keeping these steps in perfect repair. It is doubtful whether the repaired sections would have the length of life of the originals, as it is extremely difficult to bond new and old concrete or masonry in such a manner that water flowing at high velocity will not soon begin to erode the joints. Furthermore, the filling of holes with concrete so that microscopic joints can be avoided is practically an impossibility, owing to the tendency of the filling concrete to shrink away from the hole in which it is cast.

As previously stated, during the last few years much knowledge has been acquired regarding the conditions under which high velocities can be absorbed successfully or controlled by water-cushions and the burden of acting as a buffer shifted from the dam to areas more remote from the vulnerable parts of the structure and to construction more readily and satisfactorily repaired when the inevitable wear makes such action necessary.

Early in 1914, the writer performed a fairly elaborate series of experiments on models of an overflow dam to be constructed on the Little Tennessee

River, about forty-five miles south of Knoxville, Tenn. The prototype was to be 195 ft. high and the models were on a scale of 1:48. The conclusions drawn from the experiments were summarized in a report made to the Knoxville Power Company, in June, 1914, the more essential paragraphs of the conclusions being as follows:

"Practically all of the kinetic energy of water flowing at high velocities in open channels may be internally absorbed by directing the water into pools of water exceeding a certain minimum depth and a certain minimum length.

"The theoretical minimum depth of the pool is given by the equation: $d_2 = \sqrt{\frac{d_1 V_1^2}{2g}}$, in which d_1 is the depth of the water before entering the pool and V_1 is the velocity of the water at the same point. This equation gives the required depth of the pool, d_2, above the same horizontal datum above which d_1 is measured.

"The required length of the pool is at least approximately equal to the net velocity head absorbed by expansion divided by 1.35. This gives the distance in which the bottom velocity is completely absorbed. About 20 per cent. should be added to allow for complete absorption of velocities above the bottom.

"In high dams, subject to high velocities at the toe, complete absorption of the high velocities within the shortest distance possible is desirable to prevent channel erosion and turbulent conditions in tail-races, as much as possible.

"An efficient method of absorption is by directing the water into pools having the minimum depth given in preceding paragraphs.

"The height of the lip of the bucket above the bottom of the pool has little effect on the general efficiency of the absorption if the lip is kept within the lower half of the pool's depth. The bucket with the lowest possible lip will allow the least wear on the concrete, but as this is negligible on a well designed and constructed dam, the advantages of the highest possible bucket in decreasing the height through which the water falls and also allowing the use of longer buckets along the axis of the dam with less excavation and less concrete may be considered paramount. The highest possible position of the lip with present knowledge is perhaps about half the depth of the pool.

"The required depth of pool varies in the same sense as the depth of water on the crest of the dam, hence the longer the crest the shallower the required depth of the pool. The bucket must of course also be made longer.

"For the same head on the crest, arched dams, by increasing the value of d_1 for the same discharge, require greater depths of cushion pools than straight dams.

"Where pools of sufficient depth are not provided, it is probable that the entire kinetic energy of the water will be expended upon the channel and erosion will continue at a rapid rate until a pool of sufficient depth is excavated by the water."

During 1916, and, subsequently, the Miami Conservancy District made elaborate experiments that clearly demonstrated the efficiency of the hydraulic jump as a means of absorbing high velocities. The data and conclusions were published as Part III of Technical Reports, under the title, "Theory of the Hydraulic Jump and Backwater Curves and the Hydraulic Jump as a Means of Dissipating Energy". Mr. R. D. Johnson, in his discussion* of the paper, by Karl R. Kennison, M. Am. Soc. C. E., entitled "The Hydraulic Jump, in

* *Transactions*, Am. Soc. C. E., Vol. LXXX (1916), p. 378.

Open-Channel Flow at High Velocity", and in a paper* on "The Correlation of Momentum and Energy Changes in Steady Flow with Varying Velocity and the Application of the Former to Problems of Unsteady Flow on Surges in Open Channels", presents in an excellent manner the mathematical and physical conceptions involved in the hydraulic jump and the related hydraulic feature, the standing wave, and casts aside the shroud of mystery with which the every-day engineering world seems to have covered this really common and natural occurrence. It is probable that the theory of the hydraulic jump and its practical application are now fairly well understood and that few dams of any magnitude are constructed without consideration of its development and whether or not artificial means of insuring the jump will be required now or in the future.

The writer considers the ideal spillway dam to consist of a perfectly smooth-faced ogee dam, straight in plan, with the crest unbroken and designed to conform to the lower nappe of the falling water for the highest possible flood; the down-stream face of the dam to be joined to the floor of the channel by an easy curve; the channel down stream to be the same width as the crest of the dam for a distance sufficient to permit the full development of the normal jump (farther down stream the channel may be varied to suit conditions stated subsequently); the floor of the channel near the dam to be nearly level throughout, and as its position vertically is defined by the low point in the natural channel, this requirement also agrees with the one that the water should be taken through the entire fall in a single drop along the entire crest. Finally, the hydraulic functions of the channel down stream from the dam should be such as to hold the jump at the toe of the dam. Natural conditions may suffice; if not, secondary dams may be used, or the channel may be deepened artificially or be permitted to deepen naturally, as it will if sufficient depth is not provided originally.

To develop the ideal spillway economically, the dam would have to be built in a U-shaped valley. This is rarely possible, especially where very high dams are involved, the valley usually being V-shaped with respect to the dam. To meet as nearly as possible the ideal requirements, economical construction then suggests widening a certain part of the bottom of the V to permit the dropping of as much as possible of the water for the full height to provide for frequent floods and placing gates on the crest of the dam to hold the flow as much as possible within the length of crest discharging its waters directly into the cushion pool. The remainder of the crest is to be opened to flow only as required. The stepped profile may be used in these sections, or if the foundation rock is of such quality as to resist erosion well, the water from an ogee spillway may be turned over it. In either case, however, repair work from time to time will be necessary.

If gates are not permissible on the crest, a rather difficult problem is presented. If water is spilled for a considerable part of each year, the best solution seems to be in smoothing the rock surface and armoring it with concrete, the lower end of the slope to be treated the same as an extension of the dam

* *Engineers and Engineering*, July, 1922.

and the water guided horizontally into cushion pools by easy vertical curves. In any case, the direct impact of water at velocities in excess of, say, 10 ft. per sec., is to be avoided and all the water guided by surfaces made as smooth as possible into ample cushion pools.

In the cushion pool itself, very little armoring is required, as the energy is absorbed entirely by the water. Mr. Johnson has raised the interesting point that under ideal conditions in the hydraulic jump there probably is a certain quantity of water "humped up" at the bottom of the jump to form a natural weir. The inference is then that this water is practically "dead". If this is true, then high velocities are absent immediately above the channel floor and, therefore, erosion on surfaces on which the jump actually takes place is practically absent. This means that if the initial point of the jump is held on the concrete at the toe of the dam, erosion down stream from this point need not be feared, as long as the surface of the bucket and the floor of the channel are at the same elevation and the jump is actually formed. The writer is inclined to agree with this proposition. His own experiments were not sufficiently detailed to give any information on this subject. A few experiments recorded by the Miami Conservancy District, shown on page 79 of the published report, seems to confirm Mr. Johnson's theory. Several of the writer's experiments were made on models on which the horizontal edge of the bucket was about 2 in. above the floor of the channel. A favorite test was to fill the channel with sand level with the edge of the bucket and then start the water over the model after making sure that the jump would be developed. Under uniform flow conditions, the sand for several inches down stream from the bucket would not be moved, although velocities of 14 ft. per sec. prevailed within 1 in. of the edge of the bucket. Eddies, however, could be produced by slight manipulations that would sweep out all the sand and, therefore, the experiments were not conclusive.

With regard to the Gilboa Dam, it would be admittedly somewhat difficult to utilize readily the hydraulic jump throughout the entire length of structure, but it appears from such data as are available that at least two-thirds of the dam could have been built as a smooth-faced ogee spillway without difficulty and the water from this part of the crest directed into a cushion pool. It is reasonably certain that a far more efficient method of absorbing the high overfall velocities would have been utilized and the chances of future trouble greatly minimized. With a carefully designed crest, using the same free-board specified for the dam actually being built, the crest length for a maximum discharge of 110 000 sec-ft. could have been reduced to 900 ft., assuming a weir coefficient of 3.90 which is reasonable. At the maximum section, the discharge would be 121.5 sec-ft. per foot of crest, the velocity of the water at the toe of the dam about 98 ft. per sec. and the depth, at the section at which this velocity exists, 1.24 ft. According to Unwin's formula for the jump, the required depth of water to develop the jump for these conditions would be 24.8 ft. per sec., and the writer is inclined to believe that the natural flow conditions down stream from the dam would easily maintain this depth. If not, a low dam not less than 140 ft. from the main dam would be required.

Owing to the much higher elevation of the natural ground at the base of the dam toward its ends, not more than 600 ft. of the shortened crest could be protected economically by the main cushion pool. The discharge for the remaining 300 ft. of crest would have to pass into cushion pools set step-fashion at higher levels and of much more expensive construction, or down smoothed and armored slopes into the main pool, or the velocity of the water destroyed by use of a stepped profile for the dam, the actual method to be used to be developed by comparative studies.

The writer hopes to publish data on the conditions at the toes of two overfall dams 200 ft. high, completed in 1917 and 1919, respectively, which have been subjected to several floods since their completion. In certain parts and at certain times, natural water depths have not permitted the jump to develop, and high velocities have occurred resulting in considerable erosion. In time, natural cushion pools will be formed below these dams, and reasonable protection will then be obtained against continued erosive action without secondary dams. In any case, he hopes more information will be derived on the interesting problem of endowing high overfall dams with the longest possible life.

THADDEUS MERRIMAN,* M. AM. SOC. C. E. (by letter).—The writer has long been convinced that the use of accurate scale models in the solution of hydraulic problems involving dynamic effects will give better results than can possibly be secured by abstract theoretical considerations. During the greater part of the work so well described by the authors, he was in close touch with the experiments conducted by them and will refer briefly to the cause which he believes to be responsible for the dissimilarity referred to in the paper as having been observed in the behavior of models of different scales.

Water on approaching a weir crest has one free surface; but immediately after passing the crest, it has two such surfaces. For the same length of weir, irrespective of its crest width and of the depth of flow, the increase of free surface will be the same. As surface tension as between water and air is a constant for each unit of area, it follows that, when the surface is suddenly doubled, energy must be expended. The amount of energy expended in the formation of the under side of the nappe is proportional to its surface area and as this area, in turn, is proportional only to the weir length, it appears that the energy required for the formation of the under side of the nappe is not proportional to the scale of the model. It follows as a necessary consequence that models of different scales will not exhibit the same characteristics for all depths of flow over them. The thinner the sheet the greater will be the divergence from true similarity of behavior. This difference is clearly shown in Fig. 13, where the divergence for the proportionate depth of 3 ft. is materially greater than that for the proportionate depth of 6 ft.

The differences observed are due to the fact that the energy required to form the under side of the sheet is a constant for each unit of crest length. The thinner the sheet the greater will be the ratio between the energy required for its formation and the total energy in the vertical plane of the weir crest;

* Chf. Engr., Board of Water Supply, City of New York, New York City.

that is, the energy remaining per unit volume of the sheet, after the nappe has been formed will be least for the thinnest sheet, and, in consequence, the thinner the sheet, the less far it will be projected. Approaching the limit of zero thickness the nappe, instead of being projected beyond the crest, would either fall straight downward or be pulled inside the vertical. This is a phenomenon which the writer has often observed, but which is much complicated by the surface tension as between the material of the weir crest and the water which usually has a different value from that between the water and the air.

This factor of surface tension is noticeable only at shallow depths of flow, and it is only at such depths that marked dissimilarity is observed. The differences which were noted at greater depths are those naturally incident to errors of observation, which include not only the personal equation of the observer, but also differences due to changes in the direction and intensity of the wind as well as to errors in the setting of the measuring apparatus which for any one series are generally constant.

It is of interest to note that the value of the surface tension as quoted by Besant* is 7.83 mg. per mm. of length. This tension, if multiplied by the rate at which the nappe is being formed, will represent the energy required for the formation of the sheet per millimeter of its length. This energy is a small proportion of the total energy of the system and for any appreciable thickness of the nappe is entirely negligible. At low heads, however, its effect becomes noticeable.

R. W. Gausmann,† M. Am. Soc. C. E., and C. M. Madden,‡ Assoc. M. Am. Soc. C. E. (by letter).—The writers are pleased to note the valuable discussion on this paper. It seems that all the discussors agree that models in whatever sense the word is interpreted, if properly used, may give valuable information for the preparation of designs of engineering work and, more particularly, for hydraulic structures.

In the early stages of the experiment, some doubt was expressed as to the usefulness of these models, and this doubt was intensified when it was found that models of different scales did not give identical results. It was only after many experiments with models of different scales that the writers felt safe in predicting that the behavior of the full-scale prototype would approximate the behavior of a small model.

The reference made by Mr. Honness, to the experimental models of the Boonton Dam, Cross River Dam, and Ashokan Reservoir Waste Weir are very interesting, as they show, particularly in the first two instances, that models have been used successfully in the development of hydraulic structures.

Mr. Ewald has discussed certain points that were not brought out in the paper. Experience has led the writers to believe that in this climate there is a tendency for exposed surfaces of concrete to disintegrate. All masonry surfaces, therefore, are to be faced with stone indigenous to this region, which is not susceptible to weathering. The floor of the spillway channels also is to be paved with sandstone and grouted.

* "Elementary Hydrostatics", Cambridge, 1892.

† Div. Engr., New York City Board of Water Supply, Allaben, N. Y.

‡ Asst. Engr., Board of Water Supply, New York City, Cold Spring, N. Y.

On the dam, the edges of the steps are formed with stone from 6 to 36 in. in thickness, set on edge. These stones are 3 ft. deep (vertical) and from 3 to 5 ft. long (horizontal). As an added precaution, anchors not less than 5 ft. apart secure these edge stones to the cyclopean core. The treads are paved with stones from 3 to 36 in. and more in thickness (horizontal), an average depth of 21 in. (no stone is less than 18 in.), and varying lengths which must not exceed five times the thickness. The risers are faced with similar stones, except that the average width (horizontal) is 17 in. All the joints are carefully grouted and, later, will be pointed. An excellent quarry has been opened near the Gilboa Dam from which large blocks of blue-gray sandstone are readily obtainable. The minimum thickness of the stone placed to date is seldom less than 12 in. It is thought that this surface will be less subject to erosion and disintegration than concrete.

It will be noted from Fig. 4 that the grade of the channel is not excessive. The grade of the upper third is approximately 12.5%; the middle, 6.1%, and the lower third, 4.6 per cent. This diagram also shows that there is a considerable depth of water. In the part of the channel in the old stream bed, which is at the foot of the highest part of the dam, there is a depth of about 30 ft., due to a head of 6 ft. (163 cu. ft. per sec. per sq. mile). This depth due, in part, to the reconstruction of an old power dam, should provide an efficient water-cushion.

It is hoped that the theory of models may be developed more fully. At present, it seems as if practical difficulties would be encountered in making diminutive structures which would represent in detail the performances of their large-scale prototypes, but it is possible that careful study might eliminate these difficulties and that it would be possible to reproduce in miniature, the destructive effect of Niagara Falls or the effects of the propelling charge of a 16-in. gun.

In conclusion, the writers wish to express their thanks to those who so carefully discussed this paper and also their appreciation for the assistance and encouragement given by those who either directed or assisted in this work, more particularly to J. Waldo Smith, M. Am. Soc. C. E., Chief Engineer until July, 1922, Mr. Merriman, the present Chief Engineer, Mr. Honness, Department Engineer, and James A. Guttridge, M. Am. Soc. C. E., Division Engineer, all of the New York Board of Water Supply.

Paper No. 1515

THE DESIGN OF STRUCTURAL SUPPORTS FOR TURBO-GENERATORS*

By Edward H. Cameron,† Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. W. E. Belcher, Austin H. Reeves, F. A. Ericson, James H. Richardson, F. M. Beer, George A. Orrok, R. von Fabrice, D. A. Allee and Edward H. Cameron.

Synopsis

The modern turbo-generator is a highly complicated machine, subject, at times, to intricate vibrations and to forces which may attain great magnitude, owing to the high operating speed. Its structural pedestal, of concrete or steel, must provide a substantial support, both during normal operation and at times of disturbance of normal conditions.

The design of such a pedestal presents many interesting problems to the civil engineer. The restraint of vibrations and the restriction of deflections to very small amounts are the controlling factors throughout the design.

In this paper, the relative merits of the three common types of pedestals, reinforced concrete, structural steel, and composite, are discussed. A brief outline is given of the nature of the vibrations, and the suggestion is made that, in addition to the vertical impact allowance now generally used, a definite horizontal impact allowance should be adopted.

In conclusion, it is suggested that utility or fitness, rather than relative cost, should be made the sole basis of comparison in deciding on the type of pedestal to adopt for a turbo-generator installation.

When a reciprocating engine and generator is replaced by a modern turbo-generator, the operating engineer is always impressed with the marked economy

* Presented at the meeting of December 20, 1922.
† Civ. Engr., Jackson & Moreland, Boston, Mass.

of space and weight attained. The civil engineer who is called on to design a structural support for the new unit, is equally impressed with the saving in weight and space, when he compares the new foundation with that which previously served. In many instances, it is found practicable to utilize the sub-foundations of old engines for the support of modern units of many times the power of the machine replaced.

The introduction of the turbine-driven electric generator has caused the evolution of a distinct type of foundation. Where previously the support for the engine and generator consisted of a large sub-foundation and a massive superstructure, it is found possible, with the turbo-generator, to mount the unit on a comparatively light and open pedestal, with space in the basement below the machine for the condenser, circulating pump, and other auxiliaries. The absence of the unbalanced thrusts on the foundation, which occur with the reciprocating engine, has rendered this type of construction possible.

The fact that turbo-generators have only a fraction of the weight of reciprocating units of equal power, together with the freedom from the great impacts of the latter type, resulted, at first, in a tendency to slight the subject of turbine foundations. This is noticeable in some of the older reference books on power-plant design. It is now generally recognized that special problems occur in the design of such foundations, and that great care is necessary if an adequate and efficient support is to be obtained.

The generator with its prime mover is, perhaps, the most important element in the whole power plant, and principles of false economy should not be allowed to result in an inadequate supporting structure for it. The design should be made by an experienced engineer who realizes that it is much more than a problem of sustaining static loads and who is familiar with the dynamic effects of the revolving machine during normal operation and at times of accident. This supporting structure may be considered as consisting of two elements, namely, the sub-foundation below the basement floor or condenser-pit level, which may be called the "mat" or "footing", and the steel or concrete structure extending from this level to the base of the machine, which is often referred to as the "pedestal."

The type of condenser selected for the unit is a controlling element in deciding on the type and proportions of the pedestal. The value of a high vacuum was early recognized in the development of the steam turbine, and much study has been given to the construction of condensers to attain this end. At the same time, the ill effect of long piping and bends in the line between the condenser and the turbine exhaust has been emphasized, and a type of installation has been developed in which the condenser is mounted directly beneath the turbine with a resulting increase in efficiency. When financial and operating considerations result in the selection of a jet condenser for the unit, the problem of the design of the pedestal is much simplified, as there is usually ample space for the pedestal beams, columns, brackets, and bracing. The selection of a surface condenser, however, often makes necessary considerable ingenuity on the part of the structural designer to obtain a proper pedestal without interference of these members with the condensing unit.

Three types of pedestals have been evolved, as follows: (*a*) the all reinforced concrete type; (*b*) the structural steel type; and, (*c*) the combination structural steel and concrete, or composite, type.

The reinforced concrete pedestal is probably the most common type of turbo-generator support. The main advantage of this type lies in the relatively great volume of concrete in the beams and piers which have sufficient mass to absorb any vibrations that may develop in the machine, and, with reasonable care in design and construction, satisfactory operating conditions, as far as vibration in the pedestal is concerned, are practically assured. This pedestal has, however, several distinct disadvantages. The massive concrete members which are necessary to carry the loads, often seriously restrict the space required for the condenser, the ventilating air-ducts, and the piping. It is often quite difficult to secure as compact an arrangement for the condensing and auxiliary equipment as is desirable and, in general, the space below the unit for operation and dismantling will be more limited than with a steel pedestal. The weight of a concrete pedestal is several times as great as that of a steel pedestal. This results in a more expensive sub-foundation or mat, and may present a serious problem where subsoil conditions are poor.

These disadvantages have resulted in the development of the structural steel pedestal and the combination steel and concrete type, often called the composite pedestal. No sharp line of demarcation exists between steel and composite pedestals. The latter type, as generally understood, has its main members of structural steel with concrete filling between girders, a concrete deck, and, in some cases, concrete encasement of all steel members. The disadvantages noted for the concrete pedestal are largely overcome if a steel or composite design is adopted, and, it is much easier to provide members of adequate strength, at points where clearances are most restricted.

It is often necessary to defer the completion of the erection of the pedestal until the condenser has been placed, due to the space needed for erecting the latter. In such cases, the construction schedule for the plant and equipment depends on the date of the erection of the condenser. Once the condenser is placed in position, it becomes desirable to complete the erection of the pedestal as soon as possible, in order to be ready for the generator. In such cases, the fact that less time is necessary to construct a steel pedestal than one of concrete, is an argument in favor of adopting the former type.

The relative space occupied by concrete and structural steel pedestals is illustrated in Fig. 1, which shows a typical concrete design suggested by one manufacturer and a steel design for a unit of the same capacity recommended by another manufacturer. The roominess of the steel pedestal is apparent.

The tendency of the steel pedestal to vibrate with the machine constitutes its one disadvantage when compared with one of concrete, and the design of a steel pedestal proportioned so as to avoid this vibration is a difficult problem. The tendency to vibrate exists in all turbo-generators. The unit is a complex machine operating at high speed, and vibratory forces and moments may exist, due to many causes. Normally, the vibrations are restrained to negligible amplitudes by care in the manufacture of the unit and by proper precautions on the part of the operator.

Vibrations may be due to excessive bearing clearances, deflection of the spindle, disturbance of clearances at various points producing rubbing, lack of alignment, or to unbalance in the rotor caused by erosion of blades, incrustations on blades, breaking of buckets, etc. Extreme care is taken by manufacturers to correct all unbalance in the machine, and ordinarily it leaves the shop in practically perfect balance. Assuming that it is properly installed, the principal factors which will tend to produce vibrations are those which may develop in the course of its continued operation in the form of one or another of the causes stated.

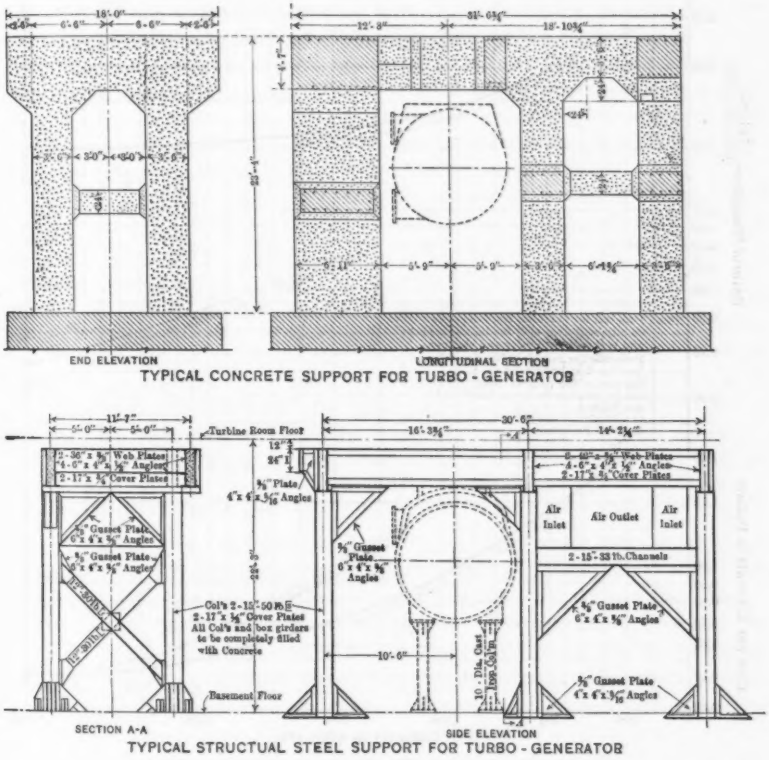

FIG. 1.

Unbalance of the rotor may occur in either or both of two forms. Static unbalance will exist when the center of gravity of the revolving parts does not lie in the geometric center of the shaft. Dynamic unbalance will occur if an unbalanced couple exists in any plane containing the shaft axis. Thus, a machine may be in static balance, but be unbalanced dynamically. The high speed of the turbine renders unbalance very serious as an unbalanced mass of 1 oz. will generate a centrifugal force of thousands of pounds.

Vibrations in the turbo-generator, from whatever cause, will be transmitted to a greater or less extent to the pedestal. If the latter is of a light, non-rigid construction, the vibrations will be amplified, resulting in serious damage to the unit. The pedestal must have mass enough to absorb all vibrations and be rigid enough to prevent swaying. If it is of great mass, the time necessary to overcome its inertia will be sufficient to consume the fractional part of a second elapsing until an impact in the opposite direction is applied, and its vibrations will be restrained to negligible amplitudes.

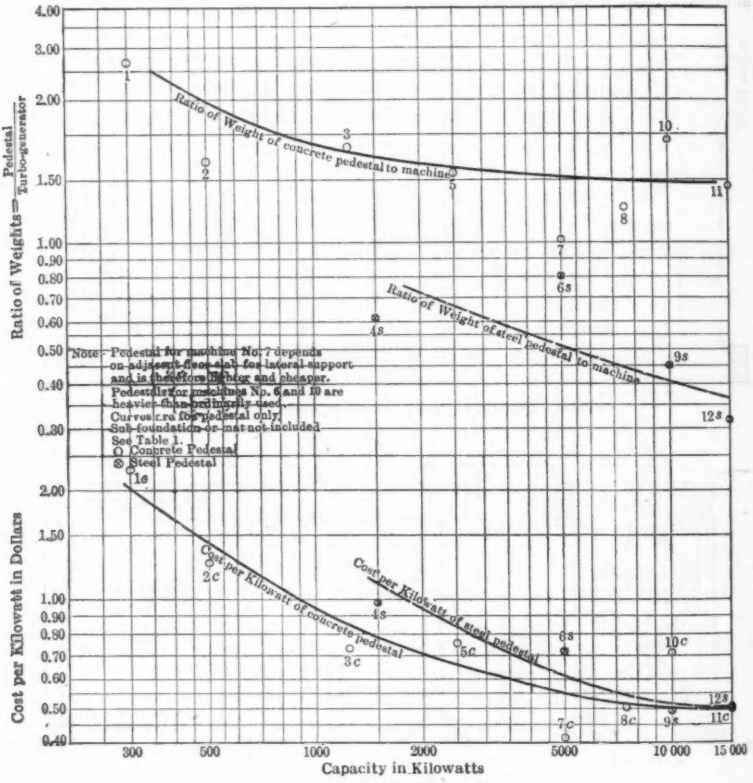

FIG. 2.

The most practical means of arriving at the requisite mass for a turbo-generator pedestal is by a study of existing designs in satisfactory operation, both as to the total mass and its distribution. In this connection, the weight-ratio curves of Fig. 2 are of interest. Each of the points plotted represents the ratio of the weight of the complete pedestal (excluding the sub-foundation or mat) to the weight of the unit supported, covering the range from 300 to 15 000 kw. Existing installations and, in some cases, typical manufacturers'

designs, have been used. The curves (Fig. 2), indicate that concrete designs, as now made, weigh from two to four times as much as steel designs. For both types, the weight ratio decreases as the units become larger.

It is not intended to convey the impression that the weight-ratio and cost curves shown in Fig. 2 will give the precise weight or cost of any pedestal that may be considered. The sources of information used are too diverse to permit of this, and the factors entering into the design are too variable to allow of such an interpretation. The only way to secure such curves would be to design pedestals over the whole range covered, with identical assumptions as to impact allowances, condensers, etc., and to compute the weight and cost of each. If this is done, it is possible that some definite law as to the variation of such factors can be deduced. The writer's intention, however, is to convey only a general idea as to the average variation of costs and weights for present designs of various capacities. It is believed that the curves represent average practice in pedestal design, as they are constructed from data obtained from installations in satisfactory operation, and, in several instances, from typical designs recommended by turbo-generator manufacturers.

It is possible to conceive of a pedestal possessing great mass, but supported on unbraced stilt-like columns so as to allow sway or oscillations of large amplitude, but of low frequency. In order to prevent this, it is necessary to introduce bracing and to make the columns capable of resisting bending. To determine the size of these members, the conception of the vibrating machine must be translated into one of equivalent forces, or specifically into horizontal and vertical forces acting at the top of the pedestal. These forces will be roughly proportional to the mass of the turbo-generator and to its acceleration in the direction of vibration. By making certain assumptions as to the amplitude of the vibrations and their frequency, it is possible to derive an expression giving the relation between the weight of the turbo-generator and the force that it exerts in the direction of vibration or sway, thus, $F = \frac{K}{100} W$. In determining K, the writer believes that practical considerations should govern, such considerations being based on design assumptions which have been found to give satisfaction in existing installations. It is certain that K will not vary directly with the speed, as it will have a maximum value at the critical speed and will be much less at higher and lower speeds. Other indefinite factors governing K are changes in the pressure of the steam, temperature variations, and changes which may occur in the condition of balance.

This impact allowance, K, is the percentage dead weight of the machine acting as transverse horizontal and vertical forces at the top of the pedestal. There is a great diversity of opinion as to the proper impact allowances. This is due partly to the failure specifically to define the allowable unit stresses, as will be noted later, and often to ignoring the horizontal impact allowance altogether. In some cases, the practice seems to have been to adopt a high vertical impact allowance, together with small working stresses, and to ignore the horizontal forces which exist. It appears more logical to assume definite horizontal and vertical forces, in addition to the dead weight of the machine, and

to adopt working stresses more nearly equal to those used in general structural design. For ordinary designs, the writer has used horizontal and vertical impact allowances varying from 33⅓ to 50% of the dead weight of the machine.

Certain general principles exist relative to the proper proportions of the pedestal to resist best the horizontal impact force noted previously. These principles can best be considered by an examination of the pedestal frame as regards vibrations. Every pedestal has a "period of free vibration", that is, a definite time which would elapse during one complete oscillation, if it was sprung from its normal position and left free to oscillate without receiving further exterior impulses. This free period of the pedestal is dependent on the size, length, and arrangement of its members and on the material of which they are constructed. Complex computations would be necessary to determine just what would be the "free period" of any one type of steel pedestal, and uncertainties as to the effect of the joints would render such computations of little value. The more rigid a pedestal is made, the shorter its natural period will be, and its members should be arranged to secure this end.

Fig. 3 represents an end view of a typical pedestal. This frame will have the shortest natural period of vibration, and, therefore, maximum rigidity, when the center of gravity of the turbo-generator and pedestal is made as low as possible, and when the ratio of $\frac{H}{W}$ is made as small as clearances and available space will permit. In some installations, a low center of gravity is obtained by hanging the condenser from the top of the pedestal and thus utilizing its mass in addition to that of the turbo-generator and pedestal. Table 1 gives the ratio, $\frac{H}{W}$, for several designs noted by the writer, together with other pedestal data. The machine numbers correspond to those used in constructing the curves of Fig 2.

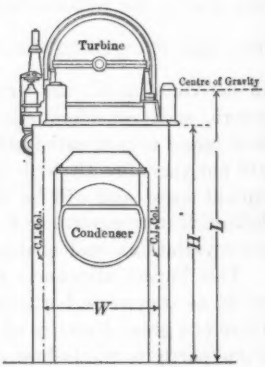

FIG. 3.

It should be stated that some designers consider it possible to have a pedestal of too great rigidity, although it is believed that all turbo-generator manufacturers concur in the desire that they be made very rigid. Comparison has been made between units resting on very rigid pedestals and instances of lathes and similar machines which have suffered from vibrations when supported directly on a concrete base. A design of a turbo-generator pedestal has been developed by Mr. N. W. Akimoff to overcome this objection of too great rigidity. In this design, the unit rests on a three-point support with heavy locomotive springs between it and the pedestal to absorb shocks. The writer understands that no pedestals of this design have been installed.

If the natural frequency of vibration of the pedestal or of any of its members equals the speed of the machine, resonance occurs. Successive impacts

will build up the kinetic energy of the vibrating pedestal, and the amplitude of the vibrations will increase until a balance is reached between the energy of each impact and that of the restraining forces, due to the stiffness of the pedestal, or of the member under consideration. Thus, resonance will result in high stresses in the pedestal.

TABLE 1.—TABULATION OF PEDESTAL DATA

A quantitative determination of vibrations induced in a turbo-generator due to non-rigidity of the pedestal has been noted.* In this instance, serious vertical vibrations in the generator bearing of a 10 000-kw. unit were detected and measured by a vibrograph. The supporting beam under the bearing and its columns were reinforced, and it was found that the vibrations were reduced to safe amplitudes.

If the speed of a turbo-generator is varied, it is observed that a certain definite speed exists at which vibrations in the unit are quite marked, although it may run quite smoothly at all other velocities. This speed at which the vibrations are so noticeable is called the "critical velocity." This phenomenon is due to the bending of the shaft under the centrifugal forces generated by unbalance, and electrical and mechanical engineers are familiar with the theories and experiments of DeLaval, Stodola, and others, demonstrating the mechanical principles involved.

The common working speeds of turbo-generators are 1 500, 1 800, and 3 600 rev. per min., depending on the cycle and number of poles. In general, the critical speed of units as now constructed is greater than the two lower normal speeds noted. However, for machines of 3 600 rev. per min., the critical speed is likely to be below the working speed, and in such cases, in starting up and shutting down, it must be passed through. Although manufacturers make special provisions in machines operating above the critical speed, it is well for the pedestal designer to make a more generous impact allowance for high-speed machines.

* *Mechanical Engineering*, August, 1922.

In addition to the transverse horizontal forces which have been considered, vibrations and impacts may exist in a direction parallel to the axis of the shaft. The unit is self-contained as far as axial forces due to unbalanced steam flow is concerned, as the thrust-bearings transmit these forces to the casing where they are balanced by the steam pressure in the opposite direction. Vibratory vertical impacts, however, will produce axial impacts if any eccentricity exists between a bearing and the pedestal member which supports it, and, in general, it is found necessary to provide longitudinal bracing as substantial as the transverse bracing.

Another source of shocks which may come on the pedestal, lies in the disturbance of the magnetic torque of the generator, which takes place during short circuits. Under normal operating conditions, the magnetic torque need not be considered, as far as the pedestal is concerned, but short circuits will cause violent fluctuations of this torque, and the pedestal will receive serious impacts.

Vacuum load	"	
Axial forces	Horizontal	At center line of shaft.

The following steps to be pursued in the design of a pedestal, are taken from standards used by the writer in the structural designs of power plants. (See Table 2.) No specific directions are attempted, as there is such a wide variation in loads, load points, construction of units, etc., for turbo-generators of different capacities and manufacture, but certain general steps are outlined for the guidance of structural designers engaged in the work, as follows:

1.—Decide on the probable type to be used: Concrete, structural steel, or composite.

2.—Preliminary layout, working from certified prints of equipment, piping, and electrical plans, to determine the best arrangement for beams, columns, and bracing, using assumed sizes. At this time, the piping and electrical layouts should be advanced sufficiently to indicate the necessary clearances for all elements adjacent to the pedestal. Investigate the approximate limits for H and $\frac{H}{W}$. H will be determined by the condenser size, floor levels, and crane clearance.

3.—Design the pedestal members in the following order, in which a 5 000-kw., Westinghouse, semi-double flow unit has been taken as an example:

(*a*) Design the slab and secondary members at the top of the pedestal.

(*b*) Compute R_1, R_2, R_3, M_1, M_2, M_3, and the shears for the main longitudinal girders; compute the average of the bending moment curves, *A* and *B*, Columns 1 and 3 (Fig. 4), to take the moments, $\frac{M_1}{2}$ and $\frac{M_3}{2}$, respectively.

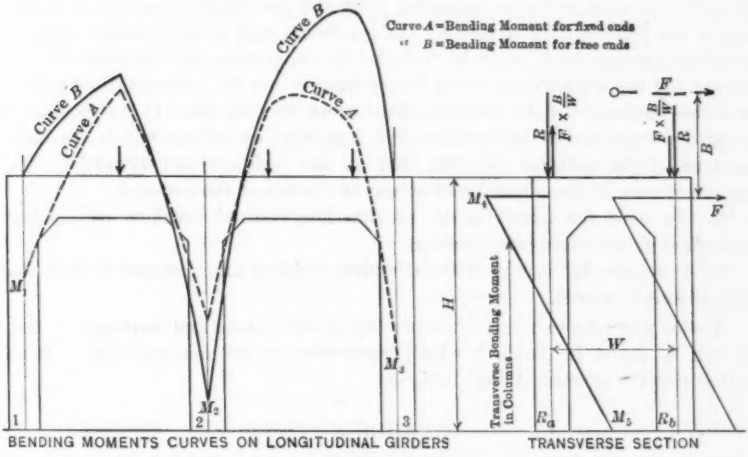

FIG. 4.

For a steel design, select by trial a beam to give a deflection, in either span, of less than 0.02 in. For a tentative value, let $f = 5\,000$ lb. per sq. in.

For a concrete design, select a beam for bending, $f_c = 600$ lb. per sq. in. Compute the deflection, maximum $d = 0.02$ in.

(*c*) Investigate the transverse bents, Nos. 1, 2, and 3, in Fig. 4:

F = horizontal impact assumed to act at the center line of the shaft.

R = beam reactions plus any loads from the unit that are directly over the columns.

Replace F by the two forces, $F \times \frac{B}{W}$, and an equal force, F, acting at the top of the pedestal.

Compute the reactions, R_a and R_b, and the moments, M_4 and M_5.

Assume the column size and check for the fiber stress, f.

Let P = the maximum vertical load on column in question.

$$\text{For Bent (1)}, f = \frac{P}{A} + \frac{M_4}{S_{xx}} + \frac{M_1}{2S_{yy}}$$

$$\text{" " (2)}, f = \frac{P}{A} + \frac{M_4}{S_{xx}}$$

$$\text{" " (3)}, f = \frac{P}{A} + \frac{M_4}{S_{xx}} + \frac{M_3}{2S_{yy}}$$

(*d*) Design the bracket, diaphragm, or braces in the transverse bent to take the direct stress or moment, or both, according to the arrangement. Design the column bases, sub-foundation mat, and remaining elements.

4.—Provision for condenser and vacuum loading: If the condenser is connected to the turbine by an expansion joint and the weight is carried from the top of the pedestal, the weight of the condenser and water content, together with the vacuum load, must be included in computing the bending moment curves. If the condenser rests on beams framed into the columns, the bending moment diagrams for the columns shown must be modified. If the condenser is rigidly connected to the turbine, and supported on springs which are independent of the pedestal, add the load on the turbine joint allowed by the manufacturers to the other forces acting at the top of the pedestal.

5.—To care for axial forces, provide longitudinal brackets or bracing equivalent to the transverse bracing.

6.—Compute the weight of the complete pedestal and compare it with the typical weight curves.

A wide diversity exists as to proper impact allowances and working stresses, as will be noted in Table 3 which gives stresses recommended by various authorities for structural steel designs.

TABLE 3.

Reference consulted.	Stress, in pounds per square inch.	Impact assumption.	Stress, in pounds per square inch, reduced to condition of dead load without impact.
1.....	One-third the ordinary.	.....	5 333*
2.....	6 000	"To take care of all loading, including impact and vibration.".....	6 000
3.....	10 000	"For the total load, to which has been added 25% of the machine loading to cover impact.".....	8 000
4.....	16 000	100% impact for all steel work.....	8 000
5.....	Halve the allowable stress and double the calculated stress.	.....	4 000*

* Based on a standard working stress of 16 000 lb. per sq. in.

As stated previously, it is believed that this diversity of opinion is due to the failure to consider the horizontal forces to be sustained. In pedestal designs, the writer endeavors to make conservative assumptions as to all horizontal forces to be considered as well as vertical dead and impact loads, and to design for these forces, using working stresses that are standard for general structural designs. This practice has resulted in designs that have proved adequate in every respect. For steel members in bending, the deflection limit will result in the selection of sizes that will give stresses that are much lower than standard.

Probably in few cases of structural design must deflections be kept within such small limits, a common value for the maximum allowable deflection being 0.02 in. A continuous beam with fixed supports will deflect least under a given load, and the longitudinal girders should be designed to secure this condition.

These girders should be made continuous over the center columns. Absolute fixity of the end supports will not exist as some deflection at these points will occur, but the true bending moment curve may be approximated by averaging the ordinates of the "free end" curve and the "fixed end" curve (see the bending moment curves, *A* and *B*, Fig. 4). Columns 1 and 3, Fig. 4, must be designed for the bending moments, $\frac{M_1}{2}$ and $\frac{M_3}{2}$, respectively, in addition to their axial loads.

In the design of connections, gussets, and other details, assumptions should be conservative throughout, bearing in mind that vibrations should be restrained in all directions. Columns should be of ample section with relatively short unsupported lengths. In order to secure this condition, brackets should be made as deep as possible at the column heads, and it is sometimes advisable to provide transverse brackets at the column bases. Structural sections less than $\frac{3}{8}$ in. thick should be avoided. The use of long cross-bracings has been criticized as they tend to allow sway before they come into operation.

Good results have been obtained with designs in which the top of the pedestal is of open steel construction, with steel plates or gratings forming a floor at this level. In such designs, it is desirable to insulate the bearing surfaces carrying the plates or gratings with cork or felt, in order to eliminate vibrations of an annoying nature in the floor. A better design, however, is furnished by making the floor in the form of a thick reinforced concrete slab. This not only produces a vibration-absorbing mat at the most effective location, but also provides a good insurance against horizontal disturbance of the alignment of the unit. If a concrete floor is used, ample temperature steel should be provided, as the temperature range is greater than that under ordinary conditions, and cracks are likely to develop.

The close proximity of the live steam lead to the exhaust outlet for some types of turbo-generators often makes it difficult to insert a longitudinal beam of adequate size in this space. In the steel design shown in Fig. 1, the longitudinal girder at the turbine end has been located outside the live steam lead, thus avoiding this difficulty. This design would be improved by making the longitudinal girders continuous over the center columns. The concrete filling between the webs of the longitudinal girders shown is a common means often adopted to secure additional rigidity and mass.

Operating engineers have observed that sudden changes in the temperature of the basement may affect the even running of the turbo-generator, due to the unequal expansion of the steel columns of the pedestal. To avoid this difficulty, these members are sometimes encased in concrete to insulate them from sudden temperature changes. Some designers consider it advisable to encase all structural steel members in concrete for fire protection and to obtain additional mass. Fig. 5 illustrates the structural steel pedestal for one of the 30 000-kw. units at the L Street Station of The Edison Electric Illuminating Company of Boston, Mass., and Fig. 6 is a photograph of the same unit in operation, with the steel pedestal encased in concrete.

The sub-foundation below the basement floor level has been referred to as the footing or mat. In its design, the disastrous effects of settlement on the

alignment should constantly be borne in mind. In some designs, separate footings have been used for the individual columns and satisfactory results obtained, but it is better practice to design the footing as a single mat large enough to include all the columns. This mat should be of ample thickness to prevent local settlement, and it is often advisable to provide steel reinforcement to secure this end. Column footings are sometimes made to rest on steel grillages encased in the mat.

Certain details are common to practically all turbo-generator installations, and the designer of the pedestal should familiarize himself with them before starting his design. The important question of clearances for the condenser, auxiliaries, and their piping, should be borne in mind, and certified prints of the apparatus should be obtained at the start so that space for operation and dismantling may be assured. At this point, a turbo-generator manufacturer may be quoted as follows:

"The foundation must not extend inside the bed-plate facing where it may interfere with the ventilating ducts under the generator, and provision must be made for these ducts communicating with the cooling air. Provision must also be made for bringing out leads under the bed-plate and through the foundations if necessary.

"Foundations must be designed with the idea constantly in mind of the complete installation of the unit and possible future repairs. Provisions must be made for the removal and replacement of parts such as oil cooler, pump, steam chest, throttle and inlet, exhaust and bleeder piping connections, and supports, and also exhaust connections, expansion joints, and atmospheric outlet piping. This means that the question of interference must be carefully gone into in connection with all parts approaching the plane of the lower surface of the bed-plate and extending below the same. The positions of the centers of loading and magnitudes and the location of loads are given on the official outline drawing sent to purchaser."

The manufacturers' plans will give dead and vacuum loads, clearances necessary for piping and air-ducts, maximum allowable deflections, anchor-bolt location, if bolts are to be used, and other information of a general nature. The instruction book for the type of unit under consideration will also be found to contain many valuable suggestions. Prints of the footing and pedestal should be sent to the manufacturers as soon as practicable for their suggestions, so that their final comments may be obtained before letting the contract for the work.

If a surface condenser is to be used, a trolley beam should be provided to facilitate the removal of the condenser head. If the generator is to be bolted down, provision should be made for removing the bolts from below in order to avoid raising the unit for dismantling. To avoid the transmission of vibrations, it is generally considered advisable to isolate the pedestal and footing from the remainder of the power plant.

Curves are shown in Fig. 2 giving the estimated costs per kilowatt of pedestals (excluding the sub-foundation or mat) for several existing installations, and for certain typical designs suggested by manufacturers of turbo-generators. Present-day prices have been used, and percentage charges, such as profit, overhead, bond, and liability insurance, are included. It will be noted that, except for the smaller sizes, there is no great difference in cost between

FIG. 5.—STEEL SKELETON FOR PEDESTAL FOR 30 000-KW. TURBO-GENERATOR.

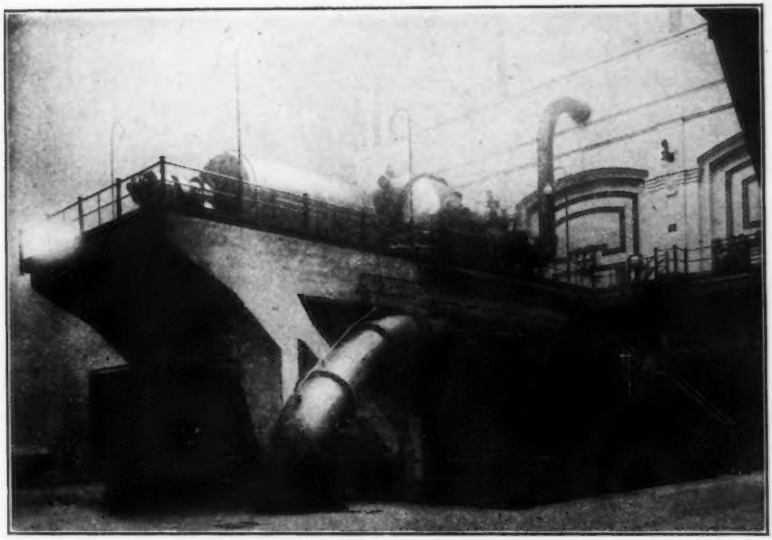

FIG. 6.—COMPLETED PEDESTAL FOR 30 000-KW. TURBO-GENERATOR.

the concrete pedestal and the steel pedestal. For ordinary designs, the cost of the pedestal should not exceed about 5% that of the turbo-generator, and, in general, any saving of one particular type of pedestal over another will not be more than about 1% of the cost of the unit which it supports. Considering the cost of the turbo-generator, and the important part in its satisfactory operation that its supporting pedestal plays as to freedom from vibrations and accessibility, it is believed that the latter's adaptability to the operation of the unit should be the only consideration in deciding which type of pedestal to adopt. Each type has its field. For the smaller units, it is believed that more concrete pedestals are in use, whereas, the reverse is probably true of the larger units. The composite type, combining the advantages of both concrete and structural steel, is coming to be more and more favored for all sizes of turbo-generator units.

DISCUSSION

W. E. BELCHER,* M. AM. SOC. C. E.—The development of the large steam turbine generator unit marks a rapid advance in the science of Mechanical Engineering, which has made necessary the special structure discussed by the author. It is to-day an appropriate topic for consideration, although ten years ago it was in its infancy, and ten years hence may have lost all practical interest.

At the World's Fair in 1904, one's attention was attracted by a loud shrieking noise which came from a steam turbine forming part of the exhibit of the Westinghouse Company. This exhibit was perhaps the introduction of the steam turbine to American engineers. For a number of years thereafter, the adoption of the turbine was very slow, the usual form being the vertical unit with capacities of 2 000 to 5 000 kw. These units were mounted on circular or octagonal concrete piers that were hollow in the center for access to the step bearings. This form was virtually confined to the impulse type of blades, and did not lend itself to expansion in the capacity of the unit.

About 1914, the manufacture of the vertical turbo-generators was discontinued, and during the last ten years, the horizontal type has rapidly been replacing all other forms of electric power generators in central station practice.

It is to be regretted that the author's paper did not show a greater range of actual design data applicable to units larger than 15 000 kw., and, in order to be of the greatest usefulness, the discussion of the paper should present examples of current practice with large units.

In the speaker's experience, single units with capacities as large as 35 000 kw. have been mounted on frames of the type described in the paper. A unit of 60 000 kw. has been installed at Cheswick, Pa., in which case, however, there were three separate turbines, one high pressure and two low pressure, each with a separate support. In designing these supports, it is the speaker's practice to use the following maximum unit stresses in structural steel members:

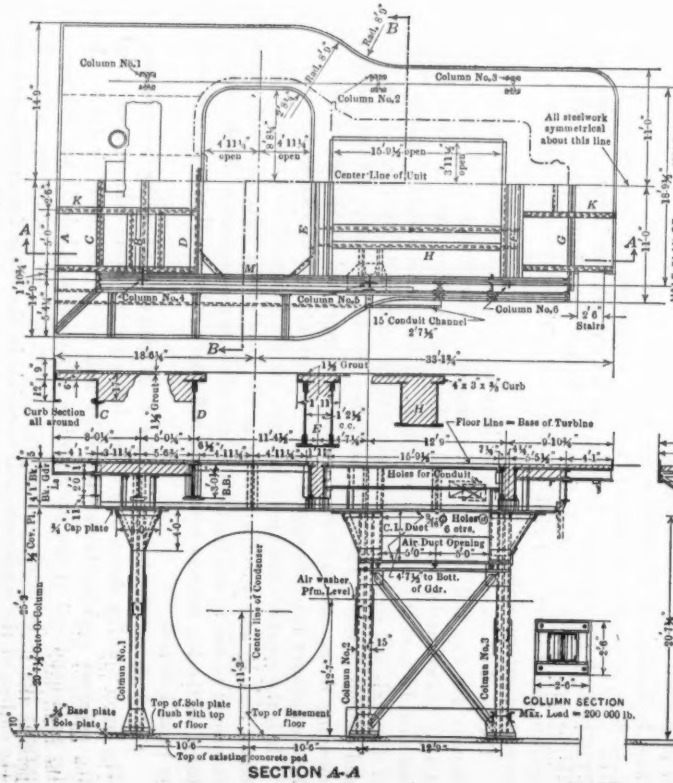
Compression on columns.....	$8\,000 - 45\,\frac{L}{R}$ lb. per sq. in.
Bending on extreme fiber of net section	8 000 lb. " " "
Rivet values, shop-driven, in shear	6 000 lb. " " "
Rivet values, shop-driven, in bearing	12 000 lb. " " "
Field driven rivets.....	four-fifths of the values given

Good judgment is more important, however, than fixed unit stresses, and the quantity of steel and concrete used should be as great as is reasonably

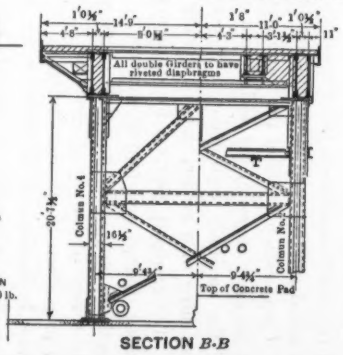
* Structural Engr., Dwight P. Robinson & Co., New York City.

justified rather than as small as possible. In erecting the machine, the top of the rough concrete slab and the steel frame are left about 1½ in. below the base casting, which is grouted in solid after all work has been aligned and leveled. Although the entire weight of the machine is in place, and carried on shims above the rough concrete slab, the framework of the support will take whatever deflection the load may cause. With this form of construction, therefore, the entire deflection is taken care of by the grouting, so that the speaker does not consider deflection to be the criterion.

The speaker believes that provision should be made for the full weight of the condenser where the connection between condenser and exhaust nozzle is bolted solidly, even if springs are placed under the condenser.



Co-operation between the mechanical and structural engineers is essential in the early stages of the design, and a slight change in the mechanical layout of the auxiliary equipment may permit the placing of a diagonal or the deepening of a girder, thus improving considerably the structural design.



The cramped quarters for equipment beneath the unit, including the condenser, pumps and piping, generator, air inlet and discharge, electrical connections, etc., make a design of reinforced concrete especially difficult. If the severe limitation of space as it develops makes one of the members out of proportion to the remainder, it is likely to cause trouble. As a result of these limitations, steel supports are generally more satisfactory. The platform floor is usually of concrete and the supporting girders are filled with concrete, both for structural bracing and for the mass resistance to vibration. This is well shown in Fig. 7, the spaces between the double girder webs and between the stringers and girders being filled with concrete, in addition to the concrete platform slab.

Every effort should be made to have the main longitudinal girders continuous for the full length of the support. The longitudinal bracing is usually placed under the electrical end of the machine, but transverse bracing must be used at each transverse bent. This bracing should be in the form of diagonals and struts, as far as possible, rather than in the form of brackets and column flexure. The entire structure should be separated from the surrounding floors, and platforms or walkways supported by slender hangers or light cantilever brackets should be avoided on account of vibration.

It is the speaker's practice to assume, for the design of the bracing, a horizontal load in any direction acting at the level of the main platform, equal in amount to one-fourth the total weight of the turbo-generator. Such a design based on the low stresses mentioned will give a substantial system of bracing in each direction.

Fig. 8 shows the foundation for a 20 000-kw. unit under construction. The larger opening shown on the top slab is for the steam exhaust nozzle, and the narrower opening is for the inlet and outlet generator air-ducts. At the right-hand end of the plate girders, a rectangular hole in the web-plate, permits the main generator cables to enter the space under the generator. The outline of the condenser shell is visible in the lower foreground, and the platform for the air washer and intake appears at the right. Fig. 9 shows

NEW ORLEANS RAILWAY & LIGHT COMPANY

FIG. 7.

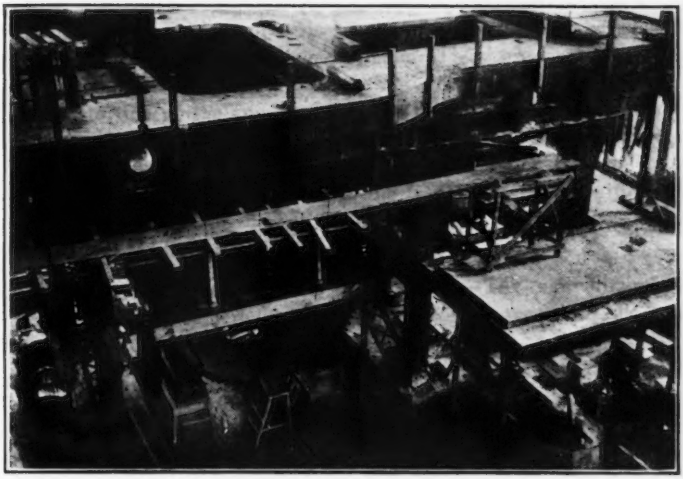

FIG. 8.—FOUNDATION FOR 20 000-KW. TURBINE, FOR NEW ORLEANS RAILWAY AND LIGHT COMPANY, NEW ORLEANS, LA.

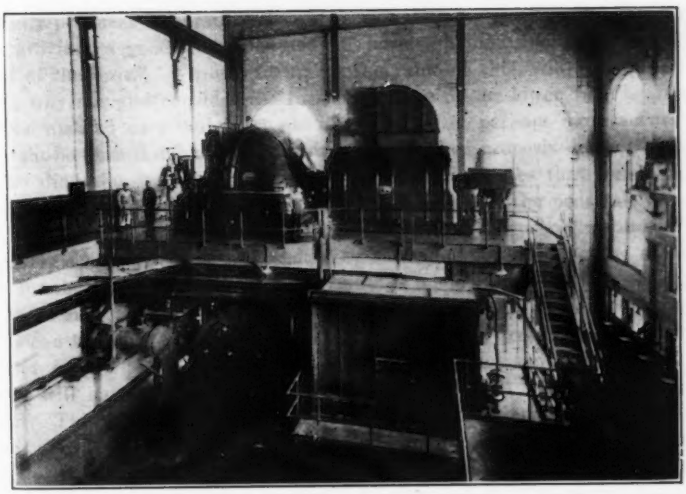

FIG. 9.—VIEW OF 20 000-KW. TURBINE IN OPERATION, IN MARKET STREET STATION OF NEW ORLEANS RAILWAY AND LIGHT COMPANY.

the general view, with the machine in operation, in the Market Street Station, of the New Orleans Railway and Light Company, New Orleans, La.

Even if a structurally perfect design has been secured, experience has shown that local conditions may cause trouble. There are cases recorded in which one column stood in direct sunlight while others were in shadow, thus causing a distortion of the frame and the destruction of the generator. In another case, distortion was caused by a cold draft at one end of the frame and considerable expense was entailed until the cause of the trouble was found. It is essential, therefore, to keep the frame at a fairly uniform temperature, and, with this in view, the steel members are sometimes encased in concrete, as noted by the author.

AUSTIN H. REEVES,* ASSOC. M. AM. SOC. C. E.—The main difference of opinion between Mr. Cameron and the speaker is in regard to the use of the "footing" or "mat". The speaker believes:

(*a*) That "separate footings" should never be "used for the individual columns";

(*b*) That it is always advisable to provide steel reinforcement in the footing;

(*c*) That steel columns should always be suitably riveted to a proper grillage in the mat or be of proper form at the base to make full use of the concrete mat. (Anchor-bolts in the ordinary sense of the word are not sufficient.)

On page 331, the author states that "a better design, however, is furnished by making the floor in the form of a thick reinforced concrete slab. This not only produces a vibration-absorbing mat at the most efficient location, but also provides a good insurance against horizontal disturbance of the alignment of the unit." While recognizing the value of this "vibration-absorbing mat", why not also consider the full, proper use of the lower "mat". It may also be utilized as a "vibration-absorbing mat", or, perhaps more accurately, it might be termed a "vibration-lessening mat" when properly designed. None of the diagrams, tables, or curves in the paper indicates that consideration extended below the top of the "mat". In speaking of the pedestals on page 326, the author states, "* * * it is believed that all turbo-generator manufacturers concur in the desire that they be made very rigid." The speaker's plea for the full scientific use of the "mat" is made because such use will give the most rigid pedestal. By proper design of the "mat", the axes of the columns can be kept vertical just above the mat, which is equivalent to reducing H and L in Fig. 3, and with the same pedestal and supported weight, the frame will have a shorter natural period of vibration, which is a desirable result. This helps in a manner similar to that of lowering of the center of gravity "by hanging the condenser from the top of the pedestal". The author has stated that "the more rigid a pedestal is made, the shorter its natural period will be, and its members should be arranged so as to secure this end." The speaker claims the "mat" is a very important "member" of the most scientifically designed foundation for the support of a turbo-generator.

* Newark, N. J.

F. A. Ericson,* M. Am. Soc. C. E.—During the speaker's connection with the New York Edison Company, and for the last few years with Thomas E. Murray, Incorporated, a variety of turbine foundations have been designed, the capacity of the machines ranging from 7 500 to 50 000 kw., in all, 558 000 kw.

The steel design has been adopted for the following reasons:

1.—It allows more room for piping and auxiliaries and, therefore, enables a greater capacity of a given space or building to be obtained, thereby reducing the cost per kilowatt.

2.—It is believed that a better, more serviceable, and more durable foundation can be built of steel than of either plain or reinforced concrete.

3.—In some cases, the space is so limited as to exclude all possibility of using any other type.

The design adopted by the speaker's Company consists of two main longitudinal girders, connected by a system of deep and stiff cross-girders and auxiliary longitudinal girders where they were necessary, in order to provide sufficient support for the bed-plate of the turbo-generator. The columns are placed directly under these longitudinal girders, with bracing inserted wherever practicable both longitudinally and cross-wise. All the girders are provided with full-depth, heavy angle connections to each other, and all connections to columns and bracing are stiff and substantial. Wherever the girders are in clusters, they are held together with bolts and gas-pipe separators, and the space between them is filled with concrete. This increases the lateral stiffness of the foundation to a great degree and also adds considerable weight, each of which tends to reduce vibrations. In designing the girders, a very low fiber stress of 5 000 to 6 000 lb. per sq. in. is used in order to minimize vibrations, and the allowable shear is reduced in proportion. Although this low fiber stress is used, nevertheless it is found necessary to increase the material in most of the girders, especially on the larger units, otherwise, the deflections would become excessive. A force proportional to the turbine load is assumed as acting in horizontal directions and is used in designing columns and bracing, but the bracing is always made extra heavy and direct acting wherever possible. All the details are designed with the idea of making a monolithic and continuous structure.

In order to avoid the possibility of unequal settlement of columns, the turbine foundation is set on a thick mat of continuous reinforced concrete, which is usually a part of the foundation for the operating room.

James H. Richardson,† Assoc. M. Am. Soc. C. E.—The speaker has had more or less to do with the designing of turbo-generator supports and wishes to present a friendly plea for the structural man as against the machine designer. The latter usually precedes the structural designer in planning power-plant units, arranging the condensers, ducts, and ramifications of pipes, large and small, often with too little regard for the structural parts of the unit.

* Structural Engr., Thomas E. Murray, Inc., New York City.

† New York City.

If the designer of the supports could rely on the strength of curved columns and sinuous girders, all might be well. As this is not the case, "let the mechanical designer allow plenty of space for the most favorable arrangement of the structural members necessary for rigidly supporting the turbo-generator unit."

F. M. Beer,* Assoc. M. Am. Soc. C. E.—Although not thoroughly conversant with turbo-generator practice, this paper brings to mind two installations, one of which is of 1 500-kv-a. and the other of 3 000-kv-a. rating, that are in use in an electric light and power plant in New York City. The supports of these units seem quite well to overcome the objectional vibrations set up while the machines are operating.

Two concrete walls of uniform thickness, parallel to the axes of the units, support transverse steel beams that carry the units. This arrangement appears best to meet the requirements of this class of equipment, as it provides the mass necessary to absorb vibration, where it is most effective and may be adapted to any size of unit. Access through these walls may be made wherever convenient and rigidity maintained even if the walls are chased or pierced to accommodate auxiliaries or piping.

George A. Orrok,* M. Am. Soc. C. E.—Since 1905, the speaker has been interested in the design of about forty steel foundations of various sizes. Most of the foundations built by the speaker's Company are of the table-top type. Two other types that are used, might be called the trestle type, in which the girders are athwartships of the turbine, and the girder type, in which two longitudinal girders not tied together rigidly, are used. In the last two types, the legs are bolted down, or an attempt is made to anchor them at the foot, which, in the table-top type, is not so necessary.

The total weight of turbine foundations should usually be adjusted to the weight of the turbine and condenser. Sufficient weight is added by concrete which is placed between the girders.

In the design of the table-top type, the deflection is kept less than about 0.006 in. Sometimes, a deflection of as much as 0.0013 in. in the frame of the machine will not cause serious trouble in its operation. Recently, a machine of 25 000 kw. capacity was placed about 1 in. above the steel cross-girder, at the middle bearing. Through some misadventure, the grouting worked loose, or disintegrated, and the steel wedges used had backed out a little, allowing the middle bearing of the turbine to drop about 0.0013 in. The turbine ran for a month or more in this condition until it could be dismantled and wedges again driven.

Whether the shaft must be level has also been a question. The speaker has noted cases where one end of the shaft was as much as 1 in. lower than the other. In these cases, a thrust-bearing was used, and the turbine worked satisfactorily.

There are four methods of supporting a condenser. Formerly, a concrete pedestal was used, an expansion joint being placed between the condenser and

* Cons. Engr., New York City.

the turbine. The concrete walls made repairs under the condenser difficult. About 1911, however, the practice was begun of hanging the condenser from the main girders, supporting the turbine on top of such girders, omitting the large expansion joint, and using expansion joints on the small water and air pipes. This made a good arrangement which is being used to a great extent at present.

In another case, spring beams were used between the columns supporting the foundation. The beams were designed so that they would spring sufficiently to allow the condenser to take its proper place. This construction has been used for nine years, without any trouble. The spring support was introduced about the same time and has been successful.

The Westinghouse Company is bringing out a new type of steel foundation. This foundation is in two parts, which allows the condenser to be placed at right angles to the turbine, with the square, or oblong, foundation supporting the generator on one side, and the turbine on the other side, of the condenser. In this case, the condenser shell is made a part of the exhaust nozzle of the turbine itself, no large expansion joints are required, but smaller expansion joints are placed on the small pipe as before.

R. VON FABRICE,* ESQ.—The author has entered a field of Civil Engineering most intimately connected with the Mechanical and Electrical Professions. As a matter of fact, the subject treats of the execution of the design of a structure, and may mean either success or failure in the proper functioning of the prime mover of the modern power station. Therefore, it is recommended that the American Society of Civil Engineers should try to formulate specific recommendations covering the various phases of the design of structural supports for turbo-generators, which could be used as a basis in executing the designs of these important structures.

Structural steel supports, as foundations for prime movers, are of comparatively recent origin, the earlier installations having caused considerable difficulty, chiefly due to lack of knowledge pertaining to the specific characteristics of the equipment to be supported. This lack of proper information was not confined solely to the civil engineer, but was shared equally by mechanical and electrical engineers. It is not an infrequent occurrence, at present, for builders to be inconsistent in their instructions and data concerning the deflection allowable, the distribution of loading, and the rigidity of the component parts of the equipment.

Most of the manufacturers do not depend on the base-plates of their equipment for equal distribution of loading, and, consequently, the base-plate serves only for centering the component parts of the unit. This, however, is only true for those turbo-generators which have a continuous base-plate. Some of the builders of larger turbo-generators do not even provide continuous base-plates for their units, and thus depend solely on the foundations or supports to hold the various parts in alignment, supplying an additional difficulty to be overcome by the civil engineer, and, incidentally, also greatly increasing the cost of the structural supports.

* Designing Engr., Public Service Production Co., Newark, N. J.

The cost of structural supports for turbo-generators having well-designed, continuous, rigid and adequate bases, is approximately 25% less than the cost for the other and more commercial types.

The main difficulties encountered in the design of the structural supports are the space limitations on account of auxiliary equipment, the limitations of allowable deflection in the structure, and inadequate provisions for the supporting or bearing surfaces on parts of the turbo-generators themselves.

The three types of pedestals mentioned by Mr. Cameron, namely, reinforced concrete, structural steel, and the combination structural steel and concrete, or composite type, are not adaptable to all kinds of installations, and the proper selection of the type to be used for any specific case is dependent on the auxiliary equipment, type of unit, space conditions, and arrangement of equipment.

The structural steel type has the greatest advantages, as it provides the most accessible arrangement for the auxiliaries and piping, and, further, possesses the greatest positive mathematical determination of design.

The composite type consists of a structural steel pedestal entirely encased with heavy concrete. The main practical advantage is that the encasement of concrete provides volume or mass, and incidentally a protection to the structural steel against temperature changes and consequent distortions of the structural frame. This last item, however, can also be obtained by a 2 or 3-in. thickness of concrete over the structural steel members, and this protection is of greatest value for the columns. The structural value of the heavy concrete encasement is uncertain, and it is advisable to ignore the value of the concrete in the calculations for strength and rigidity. Therefore, it would seem advisable to encase the steel only against temperature distortion, and design the steelwork as a purely structural support, of adequate strength for deflection and vibration.

Sudden and local temperature changes in the turbine room basement will distort the structural type of pedestal sufficiently to cause serious disturbance in the turbo-generator itself. Therefore, some engineers believe it advisable to protect the columns against such temperature changes. In any event, such protection can be obtained at a comparatively small additional cost.

The reinforced concrete pedestal is becoming less popular in modern installations, and is unsuitable for a compact and accessible arrangement of auxiliaries. Furthermore, it is impossible, in most instances, to obtain the structural strength in cross-girders, as required by the limitations of deflections imposed by the manufacturers and, also, by the inadequate bearing surfaces provided on the equipment itself at the points of most critical concentration of loading. However, this is not the case for units when continuous, heavy and properly designed base-plates are provided by the manufacturers.

Vibration in the pedestal can be reduced to the minimum in any type of pedestal, and is dependent on the proper methods of bracing, design of connections, proper detailing of connections, and primarily on the proper balancing and adjusting of the unit itself.

To provide properly against vibration in pedestals of the structural type, it is imperative that bracing in all directions be supplied, and that the

columns be secured to the grillages and girders with heavy brackets and knee-braces.

It is advisable to cross-tie the grillages so as to have at least one beam of the grillage continuous under the entire set of supporting columns in both directions, and to provide heavy brackets riveted to the column and grillage. This will stiffen the entire structure and guard against looseness in the connections between the columns and grillage. Further, all tiers of the grillage should be riveted together, and the column base should be bolted or riveted securely to the grillage.

All tension and compression members should be fabricated to provide initial tension or compression, and in practice it has been found advisable to fabricate tension members $\frac{1}{8}$ in. short in 10 ft. and compression members $\frac{1}{8}$ in. long in 10 ft. This will eliminate all possibility of slackness in the joints. It is also advisable to increase connections for all abutting members by at least 50% of the theoretical connection value, in order to provide rigidity at the joint itself and eliminate loosening of connections later. This further tends to throw the oscillations or vibrations into the members themselves, rather than into the joints or connections.

All girders composing the platform of the pedestal supporting the turbo-generator should be designed for deflection only, and the summation of all deflections of all abutting or connecting girders should result in a uniform deflection under all pedestals or bearings of the turbo-generator along its longitudinal center line.

The top of the steelwork, for a structural support, should be arranged so that at least 4 in. of concrete and grout are possible between the base of the turbo-generator and the steelwork to insure against pulverization of the grout after a period of operation.

The space between the girders of the platform should be filled with concrete in order to provide a massive mat to absorb the pounding of the unit and add to the rigidity of the joints. All parallel supporting girders under any supports of the turbo-generator should be tied together by heavy plate and angle diaphragms. Pipe and rod or standard cast-iron separators are not reliable for this purpose.

Adequate provisions should be made for foundation bolts holding the turbo-generator to the pedestal, and in cases where supporting girders come in line with holding-down bolts, a specially shaped billet, tapped for the holding-down bolt, is to be securely riveted to the top of the girder.

In the design of structural steel pedestals it is not safe to base the design on any fixed unit fiber stress as a limiting feature governing the size of the girders. Each girder should be designed purely for the proper required deflection for the load to be supported. The designer must make proper allowances for impact and distribution of loadings or weight of the unit on the various girders of the platform.

For the design of girders, three times the actual net weight of the unit has been found to be ample to provide for impact and dead weight of the structure itself. For the design of columns and grillages, three times the actual weight of the unit, together with the weight of the platform, should

be used. Grillages spanning a canal, or not being supported uniformly, should also be designed for deflection, and this deflection should be considered in the design of the platform and entire structure.

Continuous girders parallel with the longitudinal axis of the turbo-generator should be designed as such, and all positive and negative moments should be considered. Ample stiffness should be provided at all cross-connections and over columns. Turbo-generators which have a substantial, well designed, and self-supporting base-plate do not require continuous side girders, and, consequently, a less expensive pedestal can be surely designed, which can also consist of two separate structures, if so desired, supporting separate parts of the unit.

The entire structure should be supported on a continuous heavy concrete mat of adequate thickness to guard against shear and to avoid local settlement under any individual column. Steel reinforcement is required when the volume of concrete available is of limited thickness.

When setting the turbo-generator on the pedestal, it should be wedged securely to the proper alignment with steel wedges. The unit should then be grouted in place with a rich cement grout which should be poured so as to fill practically the entire hollow part of the base-plate, as this will provide for shrinkage as the grout dries and hardens under the unit. The steel wedges should not be removed, but cut off, when they extend into openings required for air ducts, piping, or other auxiliary parts.

When installations are made, care should be taken to avoid any rigid connections between the structural support of adjacent units, building wall, and building steelwork. This is primarily important in the direction at right angles with the longitudinal axis of the unit. All galleries around the turbo-generator, and secured to the pedestal structure, should have all grating and cover-plates (if any are used) bolted securely to the steelwork, in order to avoid unnecessary disturbances. If concrete floor-slabs are supported on these galleries, they should be haunched on the lower flanges of the supporting beams, to insure against loosening from the supporting steel and consequent disturbances.

The method of supporting the condensers depends largely on the size of the unit and the design of the condenser and turbine.

When an expansion joint of adequate design is used, the condenser can be supported either on pedestals from the basement floor, on steelwork connecting to the columns of the pedestal, or from hangers from the supporting platform itself. The latter method is not to be recommended, as it adds undue loading on the girders supporting the turbo-generator, and consequently increases greatly the cost of these members, on account of the small allowable deflections in these girders.

For large installations, the method of supporting the condensers on properly designed and adjustable spring supports is the most satisfactory, especially if there are provisions for testing the actual distribution of the condenser weight by suitable hydraulic jacking devices. With this arrangement, accurate distribution of loading due to the condenser is possible, and the proper amount of dead weight required by the builders on the casing

of the turbine due to the condenser is insured. Also, blocking devices should be provided to furnish proper means for supporting the condenser when filled with water for testing purposes, in order to guard against undue strains on the turbine casing under these conditions.

For new turbine-room designs, ample head-room should be allowed, in order to provide space for all auxiliaries, so as to avoid the necessity of providing pits under the equipment for condensate pumps and other auxiliaries. The following figures will provide sufficient head-room between the basement floor and top of the turbine foundation for the various units:

For	units	from	30 000	kv-a.	to	45 000	kv-a.,	or	larger....	35	ft.
"	"	"	20 000	"	"	30 000	"	"	"	30	"
"	"	"	12 000	"	"	20 000	"	"	"	25	"
"	"	"	5 000	"	"	12 000	"	"	"	20	"

D. A. ALLEE,* M. AM. SOC. C. E. (by letter).—This paper enters a field for speculation and discussion not to be lightly dismissed. Without in any way discouraging such speculation, the writer would like to present the situation as it is found to-day.

Three types of foundations have been mentioned, namely, reinforced concrete, structural steel, and a combination of structural steel and reinforced concrete, designated "composite". When designs are carefully worked out, giving due consideration to all conditions, it is believed that all types have their fields, and that any type may fairly be expected to give satisfaction; but therein lies the trouble. Which designs in practice turn out to be best? Good foundations rather than good theory are sought.

From long experience in this field, it is found that more steel structures are insufficient in their conceptions and details than is the case with concrete, as applied to turbo-generator foundations. For example, there is a tendency to use a top construction which, in itself, has no ability to maintain alignment in a vertical plane. There is also a tendency to support and grout machine bases on yielding surfaces that, therefore, allow the grout to break. An example of this is a girder with outstanding flange angles. There is, likewise, a tendency to use bracing and stiffening construction, which in themselves are quite effective, but which in practice cannot be consistently carried out, for example, heavy brackets connecting girders to columns giving the appearance of great stiffness. If, after adopting such a type of construction, it is impossible to use such brackets on one side of the foundation because the girder cannot be placed over the column, or if it becomes necessary to move a cross-girder to a position not directly over the column, as is the case with practically all turbines of a certain design, the whole principle of the design has been violated.

In general, it will be found that steel foundations are insufficient of themselves and must be tied to the floor on which they depend for support against swaying and for alignment in a vertical plane.

The composite (framed steel and concrete) design always presents difficult problems, where it is attempted to connect steelwork to concrete or to support steel on concrete. This is particularly true with large machines where loads are excessive. If steel girders are framed to steel columns and simply covered

* Civ. Engr., Constr. Eng. Dept., General Electric Co., Schenectady, N. Y.

with concrete, protection against total failure of the structure is obtained, but it is still necessary to reinforce the concrete. The function that this concrete cover performs is problematical. If the details are such (they seldom are) that dependence may be placed on the concrete, then the steel core is superfluous. In general, there is no great advantage to be gained in this construction over that of reinforced concrete.

Designs of reinforced concrete and those of all steel should be compared on a common basis. For example, referring to Fig. 1, it is quite apparent that the steel foundation is not suitable for the conditions shown in the concrete design. It is further apparent that the concrete design may be made much lighter if desired, causing the weight to be less and the clearances to be greater, but at a sacrifice of simplicity, and yet have the design the equivalent of the steel foundation with which it is being compared.

It should be kept in mind that such structures are designed by various grades of talent and, therefore, a design which would prove safe and effective, if made by a competent and careful engineer, might and probably would be unsatisfactory if developed by one less competent. Of the multitude of designs which the writer's Company examines, practically none is above criticism in the essentials of good design. It is found that poorly conceived designs in steel construction are so common that the engineers of the Company have been very reticent about encouraging their use.

EDWARD H. CAMERON,* ASSOC. M. AM. SOC. C. E. (by letter).—Two points brought out by the discussion of this paper are worthy of especial emphasis. The first is the desirability of close co-operation between electrical, mechanical, and civil engineers who are working together in power-plant design. A better foundation can be secured if the civil engineer on his part clearly understands the functions of the machine and its component auxiliaries. The mechanical and electrical engineers on their part must recognize the absolute necessity of providing space for the more important bracing elements and should be willing to modify their layout somewhat to make possible the insertion of such members. The second point considered worthy of emphasis is the importance of experience and good judgment on the part of the designer as against an attempt to adhere strictly to fixed unit stresses.

The writer believes that the present custom of fixing a limit to the deflection of members in bending constitutes a very desirable criterion of the rigidity of the pedestal. It has been stated that the entire deflection is taken care of by the grouting. The writer cannot agree on this point. Before grouting, the unit is brought to a level by steel wedges. If light girders are used, it is apparent that the relative stiffness of the girder and of the bed-plate will determine whether the driving of the wedge will tend to raise the bed-plate, or merely drive down the girder and allow the bed-plate to deflect with it. Consequently, the girders should be made sufficiently stiff that any load which they support, other than their own weight, will not cause a deflection greater than the limits ordinarily set.

Mr. Reeves is a little more positive than the writer regarding the undesirability of separate footings for the individual columns. The writer believes

* Civ. Engr., Jackson & Moreland, Boston, Mass.

with Mr. Reeves that the continuous mat should be used wherever possible; however, it is not always practical to secure this condition, and several very good designs have been noted in which the columns rest on individual footings. Both Mr. Reeves and Mr. von Fabrice have emphasized a very important point relative to the delivery and distribution of the column loads and moments into the mat. Following out the analysis given in Fig. 4, Moments M_1, M_3, and M_5, should be cared for at the column bases.

Mr. Beers mentions a type of pedestal consisting of two longitudinal concrete walls carrying transverse steel beams which, in turn, support the turbo-generator. The writer has noted several similar installations where a jet condenser was used. This design should be quite simple to build for small units as the deflections would be limited to the comparatively short transverse beams.

Several of the discussors have raised the question as to the desirability of placing reliance on the structural strength of the concrete encasement of a steel pedestal. It is very difficult and often impractical to make a theoretical analysis of the proportions of the load that would be supported by the steel member and the concrete encasement, respectively. The writer believes that the recommendation of Mr. von Fabrice that it is advisable to ignore the structural value of the heavy concrete encasement, is justified and should form a part of any conservative specification for this type of work. The concrete encasement would then be considered only for additional mass and temperature insulation.

Mr. von Fabrice quotes certain standards of shop fabrication which have been found advisable, such as making tension members $\frac{1}{8}$ in. short in 10 ft. and compression members $\frac{1}{8}$ in. long in 10 ft. There are no structures made up of the ordinary rolled steel sections in which especial refinements of common bridge shop practice are more justified.

The writer is in hearty accord with Mr. Allee in that "it is good foundations * * * that are sought". A substantial completed structure is the object of the designer in all civil engineering fields, and there is no question but that good theory based on successful practical application is the best.

In presenting Fig. 1, comparing a structural steel foundation as recommended by one manufacturer with a reinforced concrete type given by another builder, the writer did not intend to imply that the machines would be interchangeable on the foundations, or that they were precisely equivalent. The writer believes, however, that the examples selected are largely comparable and present a striking illustration of the distinct advantage of the structural steel pedestal in regard to space as contrasted with the concrete type.

In the discussion of this paper, there is a very evident preference shown by most of the discussors for the structural steel foundation, perhaps modified by the application of a concrete encasement and slab. If the manufacturers are finding steel designs to be as poorly conceived as intimated by Mr. Allee, it is high time that steps are taken to correct this condition. The writer believes that consideration should be given to the suggestion of Mr. von Fabrice that standards for the design of structural supports for turbo-generators be formulated by the Society.

Paper No. 1516

ANALYSIS OF COST OF FREIGHT SERVICE, GRAND TRUNK RAILWAY COMPANY OF CANADA

By J. P. Newell,* M. Am. Soc. C. E.

With Discussion by Messrs. J. G. Sullivan and J. P. Newell.

Synopsis

A part of the evidence presented to the Board of Arbitration appointed to determine the price to be paid by the Canadian Government for the preference and common stock of the Grand Trunk Railway Company was a study of the cost of freight service. For many years, the Grand Trunk Railway Company has sought traffic from Chicago, Ill., *via* Montreal, Ont., Canada, to New England ports, and even to New York City, in competition with the shorter American lines. This business is necessarily handled at high speed and low rates per ton-mile. The immediate purpose of the investigation was to determine whether this traffic is carried at a loss, but the methods used are here presented as applicable to the operations of any railroad, their specific application to the Grand Trunk Railway being used only for the purpose of illustration.

The general plan is one of analysis. The entire cost is assigned to various operations and, therefore, all unforeseeable happenings and accidents for the year are taken into account. The operations are divided into units, and the average cost of each is determined. In applying the results to specific cases, allowance is made for departures from average conditions. The year 1913 was selected as the latest one free from the influences of the World War.

Classification of Costs.—The cost of railroad transportation is composed of two principal elements: "Operating Expenses" and "Interest", including in the latter all charges of the same nature as interest. The Operating Expenses are divisible into Direct Costs, or those dependent on traffic, and Indirect Costs, or those not affected by traffic. Each class is also divided between the cost of Freight and Passenger Service. The cost of passenger

* Cons. Engr., Portland, Ore.

service has not been considered by the writer, except as was necessary in separating it from that of freight service.

The direct cost of freight service is divisible into two classes:

(1).—Terminal cost, or the expense of originating and delivering traffic independent of the distance moved. This cost has two subdivisions: (*a*) Carload; and (*b*) Less than Carload.

(2).—Road cost, or the expense of moving freight between the points of origination and delivery. This cost is divided between: (*a*) Distance, or the costs which are dependent on the distance moved; and (*b*) Resistance, or the costs which are dependent on the resistance overcome on account of friction and gradients.

Interest.—The interest charge is commonly regarded as "fixed", but, in reality, a considerable part is variable, increasing as traffic increases. This part is segregated and classified under the same heads as operating expenses.

Units of Service.—The next step is to determine the number of unit operations performed during the year, under each of the classes into which the costs have been divided.

The unit of Terminal Carload operations is a single terminal handling of a car, either of origination or delivery. The unit of Less than Carload operations is one terminal handling of a net ton.

The units of operation in the Distance factor are the train-mile, the car-mile, and the gross ton-mile.

The unit of Resistance is the resistance equivalent to that of lifting 1 ton 1 ft., or of 1 ft-ton.

In calculating the cost of any specific freight movement, the carload is taken as the unit. The service units connected with the movement are calculated, and the respective costs applied to obtain the total, which is then divided by the number of tons in the car, to ascertain the cost per ton, or ton-mile. The indirect cost must be borne by the existing traffic, whether it is large or small, and may be apportioned according to any desired unit of traffic.

Conclusions.—In 1913, 85% of the operating expenses and 30% of the interest was due to traffic. Passenger service was more profitable than freight.

Excluding less than carload freight, 28% of the direct cost of handling freight was terminal, 33% was proportional to the resistance overcome in moving trains, and 39% was due to the distance the freight was moved. The cost of handling an empty car was about 75% of that of a load. Increasing the number of tons per car is more effective in reducing cost than increasing the number of cars per train.

With proper study of the problem and with intelligent selection and comparison of data, the cost of transporting commodities can eventually be computed as accurately as the cost of producing them.

Division of Operating Expenses into Direct and Indirect

The first step in the study of the cost of service is the segregation of those expenses which are not affected by the volume of traffic. They form a con-

stant charge against the existing business of the railroad, whether such business is large or small.

Some expenses are affected by variations in traffic expressed by one unit and not by others. For example, the cost of trainmen is affected by changes in train-miles, but not by car-miles. Traffic, as the word is used in this connection, is understood to be measured in the unit applicable to the account under consideration, and that the variations considered are in quantity only, without change in car or train loading, seasonal distribution, balance between opposite directions, or any other characteristic which would affect cost. This is necessary in order that the effect of variations in traffic may not be confused with the effect of changes in efficiency.

Only those variations in traffic which are of considerable extent, are taken into account. There are many minor variations in the volume of traffic, which have no perceptible effect on expenses. A few more passengers or tons of freight may be carried by the same equipment at an additional cost which is negligible, but with the growth of traffic, there comes a time when additional equipment and facilities must be provided, and more men and trains placed in service. There is then a sudden increase in cost of operation, which cannot properly be attributed solely to the last additional traffic that made it necessary, but which must be spread over all the business handled. Before such a change takes place, the operating cost per unit of traffic is less than the normal cost, and afterward, for a time, it is more than the normal cost. Both extremes are disregarded in this paper. Operating expenses respond much less readily to a decrease in traffic than to an increase, and the relations determined herein are not intended to apply to such conditions.

Certain operating expenses are partly indirect, because they are due, in part, to natural causes, and, in part, to the effects of traffic. This is true of nearly all the maintenance-of-way expenses. The roadbed and all the structures are affected in varying degrees by weather, rust, and decay, as well as by wear due to the wheels passing over them. The effect of natural causes remains the same under all circumstances, but its ratio to the total expenses decreases with the growth of traffic.

Transportation expenses are partly indirect from another cause. At the beginning of operations, a certain initial equipment is required, whether or not any traffic exists. For a time, this equipment is only partly used, and a large part of the corresponding expenses is indirect. When the growth of traffic passes the point where the initial facilities are fully used, additional facilities must be provided, approximately in proportion to the increase of traffic, and, thereafter, the expenses of both the maintenance and operation of the equipment are entirely direct. Indirect transportation expenses, therefore, would ultimately disappear, if it was not for the fact that, with a growing system, the process is repeated with each addition of mileage so that although these expenses are entirely direct on one part of the system, they are largely indirect on other parts.

This consideration affects also the direct proportion of maintenance expenses, for it is obvious that if the existence of facilities has been made neces-

sary by the growth of traffic, their maintenance is also a function of traffic. It is for this reason that the maintenance of industrial tracks is considered to be a direct expense.

By ascribing the expenses of maintaining and operating partly used facilities and equipment to direct cost only in proportion to the extent to which they are used, there is charged to direct cost only the cost of maintaining and operating equipment and facilities used to approximately normal capacity. By this, it is not meant that each train is loaded with all that it can carry. In order to take care of fluctuations in the volume of business, there must be operated, at all times, equipment and facilities in excess of the average requirements. When volume of traffic reaches the point at which the excess of capacity over average requirements is only sufficient properly to take care of peak loads, the equipment is being used to its normal capacity, and further increase will demand added equipment.

In estimating the direct and indirect proportions of operating expenses, the writer has considered the various primary accounts separately or in groups of related accounts. Many of the accounts are obviously direct or indirect, either wholly or in large part. Others can be estimated only on the basis of judgment and experience. In dealing with some of these accounts, the writer has made use of a method recommended by a committee of the American Railway Engineering Association* for comparing maintenance-of-way expenses, but has extended it to include certain other accounts.

In general, the method consists in calculating the density of traffic and the expense per mile in the account under consideration, and observing the extent to which the expense on railroads of heavy traffic exceeds that on those of light traffic. For this purpose, thirty American railroads have been selected, the majority of which are in the northern part of the United States and operate under conditions fairly comparable to those of the Grand Trunk Railway. Roads, the business of which is confined principally to freight or to passenger service, have been excluded.

The volume of traffic and the expense for each railroad for a given year was found from the records of the Interstate Commerce Commission. In each case, the roads have been divided into two groups, those above the average density of traffic and those below it. Assuming that the difference in expense in the two groups is proportional to the difference in traffic density, the percentage of the given expense due to traffic at any given density, has been calculated. By this means, all comparisons between large and small volumes of traffic are confined to the same period of time, thus avoiding the complications due to rising and falling prices and wages.

I.—Maintenance of Way and Structures

In applying the method of analysis described, the chief difficulty is in choosing a unit of traffic that is related closely enough to the expense under consideration, and in equating the units in freight and passenger service. The Committee of the American Railway Engineering Association, previously mentioned, recommends that for consideration of track-maintenance expenses,

* *Proceedings*, Am. Ry. Eng. Assoc., 1913.

what it calls "Equivalent Ton-Miles", shall be used to measure the density of traffic. That Committee estimates the damage, per ton-mile, to track caused by passenger trains as being twice that of freight trains, and the damage from locomotives as twice that of cars. Therefore, the passenger-locomotive ton-miles is multiplied by 4, the passenger-car ton-miles and the freight-locomotive ton-miles, by 2, and the products are added to the gross ton-miles of freight cars. The total is the equivalent ton-mileage. From consideration of a number of railroads, that Committee has derived a formula for determining the normal percentage of any expense which is direct for a given density of traffic, as follows:

Let X = amount of indirect maintenance per mile of track.
C = total maintenance per mile of track.
M = millions of equivalent ton-miles per mile of track.
I = increase in maintenance per mile for an increase of 1 in the value of M.
R = ratio of I to X.

Then, $X + M\,R\,X = C$, and $\frac{100\,M\,R}{1 + M\,R}$ = the percentage of C, which is direct. The equivalent ton-mileage of the Grand Trunk Lines in Canada for the year was found to be 21 585 000 000. On the basis of 3 118 miles of railroad, the value of M was 7, and on the basis of 3 825 miles of main tracks, it was 5.7.

The various primary accounts have been divided as follows:

6.—Roadway and Track.—A study of the statistics of the Interstate Commerce Commission for recent years, in which this account has been divided into two parts, shows that about 30% of it consists of the care of the right of way, which is not affected by adding more tracks. In compiling Tables 1 to 11, inclusive, the writer, therefore, has measured the density of traffic by dividing the equivalent ton-miles by the miles of main track, but for measuring the expenditure, 70% of the other main tracks has been added to the first, calling the sum "Equivalent First Main Track", and dividing this into the amount spent for maintenance. Side-tracks have not been included for the reason that investments in yard and industrial tracks are due to the increase in the traffic over that which existed when the road was built and, consequently, all maintenance expenses on those tracks must be considered as direct. The same thing is true, in part, of passing tracks. Table 1 shows the method of deducing a ratio from the records of the Interstate Commerce Commission. The equivalent ton-miles are calculated from the net ton-miles and the locomotive and car-miles.

The average density of traffic was 5.71 million equivalent ton-miles. The roads with a greater density had an average of 9.30 million, with an expense per mile of $778. Those with less density averaged 4.34 million and an expense per mile of $504. If a difference in traffic density of 4.96 million meant a difference in cost of $274, a difference of $M = 1$ would mean $55.

The part of the expense per mile of the second group, which was due to traffic, was $4.34 \times \$55 = \$239$. The remainder, \$265, was indirect, and is represented by X in the formula, whereas,

$$R = \frac{I}{X} = \frac{55}{265} = 0.21.$$

As $M = 5.7$, the direct percentage is,

$$\frac{100\,(5.7 \times 0.21)}{1 + (5.7 \times 0.21)} = 55\%.$$

The average for the three years, 1911, 1912, and 1913, was 60%, which was accepted as the true ratio. Fig. 1 illustrates Table 1.

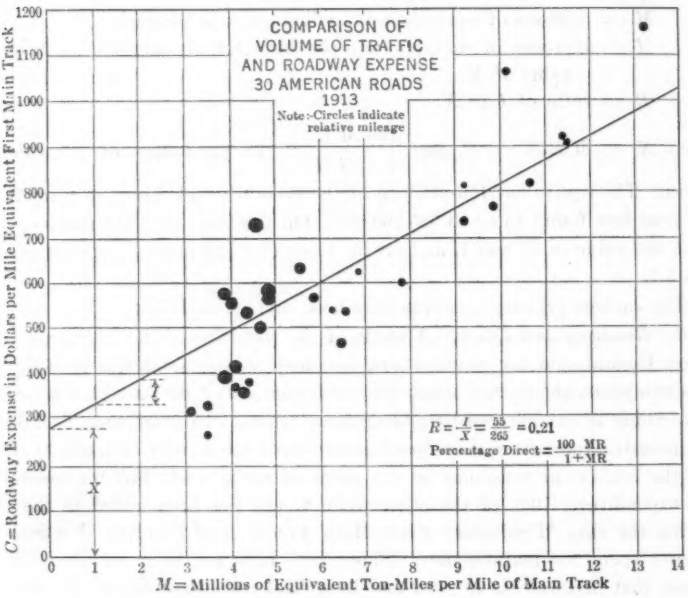

FIG. 1.

3.—Ties.—The cost and durability of ties varies so widely, and there are such differences in the practice of the various railroads in the preservation and protection of ties, that the writer has not relied on comparisons with other roads, but with the assistance of engineers familiar with the Grand Trunk Railway and the character of its maintenance, he has made estimates of the relative effects of traffic and natural causes on each section of the line. In this way, the tie maintenance of the System was classified as 34% direct.

4.—Rails and 5.—Other Track Materials.—In the case of these accounts, deterioration from any other cause than wear is so small that it may be ignored entirely, and the whole account treated as direct.

TABLE 1.—EFFECT OF VARIATIONS IN TRAFFIC ON ROADWAY AND TRACK MAINTENANCE, 1912.

Railroad.	Miles of railroad.	Miles of other main tracks.	Miles of equivalent first main track.	MILLIONS OF EQUIVALENT TON-MILES.		ROADWAY AND TRACK.

9.—Bridges, Trestles, and Culverts.—The maintenance of culverts is not affected by traffic, and that of trestles very little. Steel bridges are very little affected by the elements, the principal indirect expense being for painting. The cost of retirements, which are due almost entirely to wear under traffic or to increase in weight of rolling stock, is direct. Records of the Grand Trunk Railway Company show retirements of steel bridges charged to operating expenses amounting to nearly one-half the total maintenance in 1913. The account, therefore, is estimated as 50% direct.

16.—Buildings, Fixtures, and Grounds.—Owing to the lack of any other basis for estimating the percentage of direct maintenance, recourse was had again to the records of other railroads. After much study, it was decided that equivalent ton-mileage although not directly affecting the maintenance of certain kinds of buildings, was, nevertheless, a sufficiently reliable standard by which to measure traffic density, and, accordingly, it was used in the same manner as it was for "Roadway and Track", except that miles of road and not of track were used for measuring both density and maintenance. For the three years, 1911-13, the records show an average value for R of 0.86. The value of M was 7.0, which makes the account 86% direct.

Other Expenses.—Of the remaining accounts under "Maintenance of Way", some are entirely indirect; some are small in amount, and have been assigned on somewhat arbitrary bases; and others are of a general nature and are apportioned according to the average of all accounts which can be directly assigned. They are combined in Table 2 as a single item.

II.—Maintenance of Equipment

The accounts under this group are nearly 100% direct. There is a slight reduction on steam locomotives, repairs, because of indirect train mileage (see Account 62, "Dispatching") and, in freight cars, repairs, a small allowance is made for decay.

III.—Traffic

This group of accounts was estimated to be 52% direct.

IV.—Transportation Expenses

The expenses in this group are most readily apportioned by segregating them first, as between freight and passenger and then segregating each, as between direct and indirect. Practically the entire group would be direct, if it was not for branch lines on which the traffic is below the capacity of minimum service permissible. At the beginning of operation, each district must be given an amount of service adequate for the needs of the public, which will require only a small number of short trains. For a long time thereafter, the growth of traffic is taken care of by adding cars, with no change in the number of trains, and, consequently, no effect on those expenses dependent on train mileage.

Certain accounts are variable, chiefly according to car mileage. As soon, therefore, as it becomes necessary to add more cars, those expenses become wholly direct. Fuel, water, lubricants, and other supplies for road locomo-

tives, are partly, but not proportionately, increased by that growth of traffic which can be cared for by additional cars alone, and do not become wholly direct until increased train mileage becomes necessary.

62.—Dispatching.—This expense is apportioned between freight and passenger service on the basis of train mileage; in accordance with the rules of the Interstate Commerce Commission, 56.3% is apportioned to freight.

It may be fairly assumed that as there was a large volume of travel on the main line, the passenger service was only that which was reasonably required to meet the demands of traffic, and that any substantial increase in traffic of the same character and having the same daily and seasonal distribution would have required additional train service. All main-line passenger-train expenses were, therefore, direct. The maximum number that could be averaged on branch-line passenger trains was taken as 4 cars, besides the baggage car; the actual average was 3.5 cars. These trains, therefore, were operated at 87.5% capacity, as it is fair to conclude that no more cars were hauled than the traffic required, although there is no doubt that the cars were only partly filled over much of the mileage. The two mileages were nearly equal so that of the two combined, 93.5% was direct, and this percentage was applied to the dispatching of passenger trains.

Freight trains are also of two classes:

1.—Through freight trains on the main line and important branches. It is assumed that through freight trains are not sent out until sufficient tonnage is available to make up full trains. All these expenses are, therefore, direct.

2.—Way freights and mixed trains, constituting the whole service on many branches and a part of it on the main line. The latter is estimated to be 100% direct, as it is all greater than the minimum amount required to give sufficiently frequent service, and the trains no doubt are as heavy as practicable, considering the equipment used, the grades encountered, and the nature of the service. Branch-line way-freight trains were found to haul about three-fourths as many cars per train as main-line way freights. The latter trains both discharge and pick up freight while moving in either direction, but a branch-line train does nearly all its unloading while moving from the main line, and its picking up, in the opposite direction. This accounts for a part of the difference in train loading; therefore, the branch-line way freights have been estimated to be 80% direct. Mixed trains were estimated to be 38% direct.

The total freight-train mileage was 11 026 000, classified as follows:

Through freight.....	8 762 000	miles,	100%	direct	=	8 762 000
Main line way.....	1 506 000	"	100%	"	=	1 506 000
Branch line way.....	446 000	"	80%	"	=	356 800
Mixed trains.....	312 000	"	38%	"	=	118 560
Total	11 026 000	miles,	97.4%	direct	=	10 743 360

This makes the total mileage 97.4% direct, which percentage is to be applied to all freight-train expenses. Together with the percentage of 93.5 for passenger trains, it makes the account of "Dispatching," 95.5% direct.

63.—Station Employees.—At small stations, a minimum force must be employed, but the traffic is often insufficient to keep such a force at work to full capacity. Usually, some additional traffic could be cared for at any station, without increasing the number of employees proportionately. Only an intimate acquaintance with the station work on every part of the System would enable one to make a reliable estimate of the extent to which this is true. The writer, therefore, has had recourse again to what for convenience may be called the "A. R. E. A. formula". The proper units for measuring growth of traffic for this purpose are the ton and the passenger, which has been equated on the assumption that 2 passengers equal 1 ton.

In 1912, thirteen of the roads given in Table 1, with an average traffic of 23.08 million "equated" tons per mile, spent $1 370 per mile for station employees. The corresponding figures for seventeen other roads are 4.38 million "equated" tons and $455 per mile for station employees. This gives a value for R of 0.20. Similar calculations give values for R equal to 0.21 and 0.19, respectively, for 1911 and 1913. On the same basis, the value of M is 8.5, and the percentage of direct, therefore, is 63. If 1 passenger is assumed as equivalent to 1 ton, the result will be changed only 1 per cent.

At some of the stations, the employees are directly assignable to freight or passenger service. These are estimated at 80% direct, and the remainder fixed at 53%, in order to make the total 63%, as previously given.

66.—Station Supplies and Expenses.—By the same method, this account is fixed at 73% direct.

67 to 76.—Yard Expenses.—These expenses are dependent on the number of cars handled, and the entire group of accounts, therefore, is considered to be 100% direct.

80.—Road Enginemen.—Direct assignment from the payrolls shows this account to be 70.6% freight and 29.4% passenger. Each account is direct in the ratio determined for train mileage under "Dispatching". This makes the entire account 96.3% direct.

82.—Fuel for Road Locomotives.—Fuel is assigned directly to freight and passenger service in the accounts of the Company, in the ratio of 70% freight to 30% passenger. The consumption of fuel while the train is in motion is directly proportional to the tonnage moved. A considerable quantity of the fuel is consumed by stops, road-switching, and waiting at stations. Such losses, however, will increase even faster than the increase in traffic, as the number of stations will be increased and more delays will be caused by trains meeting. The only coal consumption which is not direct, is a part of that accompanying train service not used to capacity. The coal consumption of way freights per train-mile was about the same as that of through freights, the fuel used in stops, waits, and road-switching making up for the lighter tonnage. Fuel consumption in freight service, therefore, was direct in the same ratio as train mileage, or 97.4 per cent.

Branch-line passenger trains were assumed to use three-fourths as much fuel per mile as main-line passenger-trains, so that the fuel consumption was

calculated to be 94.3% direct. Application of the ratios thus found, to freight and passenger service gives 96.5% of the entire account as direct.

Water, Lubricants, and Other Supplies.—These accounts are given the same classification as "Fuel".

88.—Road Trainmen.—Assignment direct from the payrolls shows the ratio in this case to be 72.3% freight and 27.7% passenger. Each service is direct in the ratio found under "Dispatching", namely, passenger, 93.5% direct, and freight, 97.4% direct. Applying these ratios, the entire cost is 96.3% direct.

89.—Train Supplies and Expenses.—The expenses in this group consist chiefly of cleaning, lighting, lubricating, and icing cars. Each expense is variable practically in accordance with the number of cars handled, therefore, the whole account is direct.

99.—Loss and Damage, Freight.—This account is entirely direct.

V.—General Expenses

These expenses are usually thought of as practically a fixed charge, but this is far from true. As traffic increases, employees are added in all general offices, new departments are instituted, and larger salaries are paid. These expenses have been apportioned by the writer on the average of all other Accounts 1 to 105, inclusive, which gives 85% direct.

Table 2 summarizes the analysis thus far, showing that, in 1913, 85% of the expenses of the Grand Trunk Railway Company was direct; that is, if the traffic had been 10% more or less, with the same character and distribution, the operating expenses would have been similarly changed 8.5 per cent.

The percentage of direct operating expenses is usually estimated at a much lower figure, but a study of the statistics of the Interstate Commerce Commission bears out these results. Indeed, if revenue is taken as the measure of tonnage, it will be found that the expenses of the larger carriers exceed those of the smaller ones in practically direct proportion to their traffic. The same conclusion must be drawn from the fact that operating ratios average approximately the same among roads of light and of heavy traffic. Revenue, however, does not accurately measure traffic, otherwise, one would be obliged to conclude that operating expenses are 100% direct.

Division of Operating Expenses Between Freight and Passenger Service

The rules of the Interstate Commerce Commission for the separation of operating expenses cover this subject so completely that the writer will not discuss it, except where he has departed from those rules.

I.—Maintenance of Way and Structures

Direct.—The rules of the Interstate Commerce Commission divide track-maintenance accounts on the basis of fuel used in the two services. In the present case, this rule would give 70% for freight, but the writer thinks that equivalent ton-mileage, as used by the American Railway Engineering Association, furnishes a better basis, and it has been used for all railroad tracks,

thereby assigning only 60% to freight. Maintenance of yard tracks and sidings is divided according to locomotive switching mileage, 90% freight. The different classes of tracks are equated, in maintenance expenses, for each account, as follows:

Ties:

1 mile of main track = 2 miles of yard tracks = 1⅓ miles of passenger tracks.

Rails:

1 mile of main track = 4 miles of yard tracks = 2 miles of passenger tracks.

Other Track Material:

1 mile of main track = 1 mile of yard track = 1 mile of passenger track.

Roadway and Track:

1 mile of main track = 3 miles of yard tracks = 2 miles of passenger tracks = 1.4 miles of second tracks.

The calculations are omitted for the sake of brevity.

Indirect.—The indirect maintenance-of-way expenses are not only independent of the volume of traffic, but also of its nature. There is nothing about the decay of a tie or the removal of snow from the track which attaches the expenses to freight as against passenger traffic, or the reverse. These expenses, therefore, cannot be apportioned on any special basis. They must be assigned arbitrarily, and the best basis for such assignment would seem to be that of the results obtained in each service. These results are indicated by the revenues, provided rates are properly adjusted as between the two services. This adjustment is most nearly correct when the earnings in each branch of the service bear the same relation to the direct cost in that branch. The indirect maintenance-of-way expenses are apportioned, therefore, in the same ratios as the total direct operating expenses, namely, 72.5% to freight, and 27.5% to passenger.

Table 3 shows the separation between freight and passenger service for both direct and indirect. The same ratios have been used for both, except as noted, or in certain transportation accounts, where the assignment is affected by the fact that one service is more completely direct than the other.

Direct Freight Operating Expenses, Division Between Terminal and Road

Definitions.—Terminal expenses are those incurred in the origination and delivery of traffic, without regard to the distance it is moved. They consist of loading, unloading and accounting for freight shipments, switching cars to and from industrial sidings, making up trains, in short, of all expenses by which freight is placed on the main-line track, ready to move, or taken from its position in the train to the consignee. They are divided into two classes, Car Load and Less than Car Load. All expenses incident to the movement of car loads of less than carload freight are included in the first class. The

second class contains only those expenses peculiar to less than carload. ("Terminal", as the word is used in this paper, does not refer to the ends of the road.)

Road expenses are those incurred in the moving of freight between the stations of origin and destination. They are of two kinds, namely, those proportional to the distance the freight is moved, called Distance Expenses, and those dependent on the physical resistance to movement, or Resistance Expenses. Distance is subdivided, according to the unit directly affected, into train-mile, car-mile, and gross ton-mile.

Costs are not necessarily classified by their causes, but by the factors in accordance with which they are variable. For instance, the expense of enginemen is incurred solely on account of Resistance, but is assigned to Distance, as the men are paid according to the miles run.

I.—Maintenance of Way and Structures

2 to 6.—Track Accounts.—Yard tracks and sidings are used for both origination and delivery of freight, which is a terminal expense, and, at division points and junctions, for operations connected with through movements, which belong to distance expenses. No accurate apportionment can be made between the two classes, but it can be approximated closely enough for the purpose of this paper.

The amounts of freight originated and delivered at each division point were known and from calculations of tonnage moved east and west, the tons into and out of each point were ascertained. The respective percentages of local and through tonnage were then calculated for each division terminal. The trackage at each point was next measured. After deducting the local tracks, which include team tracks and those serving freight-houses, stock-yards, warehouses, and industries, the remainder was divided between through and local service according to the percentages stated previously. In this way, the tracks of Grand Trunk Railway were classified, as follows:

	Miles.
First main track	3 118
Second main track	707
Passing tracks	231
Yard tracks used in through service	217
Yard tracks used in local service	182
Local tracks and sidings	597
Total	5 052

These figures were used for subdividing track maintenance expenses.

3.—Ties.—Of the direct expense which was apportioned to freight, 42% was on account of yard tracks and sidings. The maintenance of that part of those tracks which is used in local service is terminal, whereas that of the remainder, being proportional to the weight of cars handled, is charged to gross ton-miles. On account of less traffic over them, the writer has estimated that local tracks and sidings require only two-thirds as much tie maintenance per mile as yard tracks. The proportions are, therefore, as follows:

	Terminal.	Gross ton-mile.
Yard tracks in through service	...	217
Yard tracks in local service	182	...
Local tracks and sidings ($597 \times \frac{2}{3}$)	399	...
Total	581	217

The 42%, therefore, is divided into terminal carload, 31%, and gross ton-mile, 11 per cent. The remaining 58% is apportioned according to the equivalent ton-mileage in freight service, which was:

Locomotive ton-mileage	3 747 000 000
Gross ton-mileage	9 268 000 000
Total	13 015 000 000

The former belongs to resistance, 17%, and the latter to gross ton-miles, 41 per cent. The entire account, therefore, is apportioned:

Terminal carload	31%
Gross ton-miles	52%
Resistance	17%

The other track accounts are treated in the same manner, but the results vary, because of different values assumed for local as compared to yard tracks, which are, as follows:

Rails	1	mile	of	local	tracks	=	½	mile	of	yard	tracks
Other track material	1	"	"	"	"	=	½	"	"	"	"
Roadway and track	1	"	"	"	"	=	⅓	"	"	"	"

Because of variations in the proportions of maintenance due to yard tracks and sidings under each account, there is further difference in the results. The percentages apportioned to each classification are shown in Table 5.

9.—Bridges, Trestles, and Culverts.—These accounts were apportioned on equivalent ton-mileage, as was done with road tracks: Gross ton-mile, 71%, and resistance, 29 per cent.

16.—Buildings, Fixtures, and Grounds.—Station and office buildings are apportioned in the same manner as "Station Employees".

Roadway buildings are apportioned in the same proportion as "Track Accounts" and "Bridges", combined.

In the case of fuel stations, the ratio of direct freight fuel used in road service to all fuel charged to direct freight is 83 per cent. The same percentage of the maintenance of fuel stations is charged to resistance, and the remaining 17% is divided in the same manner as "Yard Expenses".

Water stations are apportioned in the same manner as fuel stations.

Shops are apportioned in the same manner as maintenance of equipment.

Engine houses are apportioned to resistance according to the proportion of engine-house expenses-road to total direct freight engine-house expenses, 73%, the remaining 27% to be divided the same as "Yard Expenses".

The apportionment of the various parts of the primary account gives, for the total: Terminal, less than carload, 27.8%; terminal, carload, 17.2%; train-miles, 3.2%; car-miles, 14.0%; gross ton-miles, 1.5%; and resistance, 36.3 per cent.

II.—Maintenance of Equipment

25.—Steam Locomotives, Repairs.—This expense is assigned according to locomotive mileage, whether road or yard. The former is 71% of the total, and this percentage, therefore, is charged to resistance. The remainder is

divided the same as "Yard Expenses," according to the switching mileage in terminal and through service.

34.—Freight-Train Cars, Repairs.—Mr. B. F. Zercher, former Master Car Builder at the Angus Shops of the Canadian Pacific Railway Company, and recently holding a similar position on the Grand Trunk Western Railway, who has given special study to the causes of damage to freight cars, estimates that 65% of all damage occurs in yard handling, 3% is due to curvature and grades, and the remainder is about equally divided between the starting and stopping of trains and causes independent of track or handling. Accepting his estimate (except for a small increase in amount due to resistance of curvature and grades), the writer has divided the yard handlings between Terminal and Distance in proportion to switching-locomotive mileage (see "Yard Expenses"). The apportionment of the entire account is as follows:

Handling local cars in yards (Terminal)	38%
Handling through cars in yards (Distance)	27%
Starting and stopping trains (Distance)	15%
Miscellaneous causes (Distance)	15%
Effects of curvature and grades (Resistance)	5%

The distance expense belongs to car-miles.

III.—Traffic

All expenses under traffic (Accounts 53 to 60), are terminal, and one-fourth has been apportioned to less than carload, and three-fourths to carload.

IV.—Transportation

62.—Dispatching.—This is entirely a train-mile expense.

63.—Station Employees.—The greater part of these employees are engaged in terminal operations, the principal exceptions being telegraph operators and men engaged in feeding and watering stock, straightening and reloading shipments, and other work connected with through business and the accounting therefor. These expenses are estimated as 15% of the entire account, which is divided between train-miles and car-miles.

Of the 85% terminal, the greater part belongs to less than carload business. Carload business requires only accounting, billing, weighing, occasional loading and unloading, and a proportion of the general expenses of the station. The writer estimates this as about one-sixth of the terminal charge. The account is apportioned as follows: Terminal, less than carload, 70%; terminal, carload, 15%; train-miles, 8%; and car-miles, 7 per cent.

66.—Station Supplies and Expenses.—These expenses are apportioned in the same manner as "Station Employees".

67 to 76.—Yard Expenses.—On account of greater average distance to be moved, smaller number of cars to be handled at one time, and the necessary movements of the empty car, 1 ton delivered to consignee, to team, or transfer track, or to freight-house, has been estimated as requiring as much switching service as 2 tons passing from one division to another. Weighting the local tonnage at this ratio, the switching-locomotive mileage at each point has been

apportioned between local and through service. The former required 58.6% and this percentage of the yard expenses, therefore, is charged to terminal carload. The remainder is assigned to car-miles.

80.—Road Enginemen.—Although enginemen are employed because of the resistance to be overcome, the expense on this account is variable in accordance with variations in the resistance only as far as it causes helper or assistant engines to be used. Freight-locomotive mileage exceeded freight-train mileage by 20.3%, therefore, this proportion is charged to resistance and the remainder to train-miles and terminal. The time spent in switching cars or waiting for less than carload freight to be loaded or unloaded is terminal. The percentage of time chargeable to each of these causes is estimated under Account 82 ("Fuel for Road Locomotives"), from which the following apportionment is made:

Train-miles (running)	42.0%
Train-miles (delays)	25.3%
Terminal carload (switching)	6.2%
Terminal, less than carload (waiting for less than carload)	6.2%
Resistance (helper service)	20.3%

82.—Fuel for Road Locomotives.—Fuel is consumed by road locomotives when engaged as follows: (1) Firing up; (2) pulling trains; (3) running down hill by gravity; (4) waiting at meeting points and terminal delays; and (5) waiting while freight is being loaded or unloaded.

Item (1) should be divided in the same proportions as the remaining uses and, therefore, may be omitted from this calculation; it amounts to about 3% of the total. Item (2) is clearly chargeable to resistance. Item (4) is indirectly dependent on resistance, as the greater the energy required, the more engine service is needed and the larger the waste of fuel in delays. It also varies with distance, as the longer the run the more time wasted in delays. The quantity of fuel thus consumed, however, is very small, and, therefore, the factor of distance is ignored herein. The fuel consumed while running down hill may be considered as an addition to that consumed while climbing the same grades, and charged to resistance. Fuel burned while less than carload freight is being loaded or unloaded, or cars picked up or set out, is a terminal expense.

In the following estimate of time consumed in various ways by freight-train locomotives, the percentage of time actually running is taken as 100, and is assumed to be the same for all trains. The velocity profiles of the main line from Chicago, Ill., to Portland, Me., show that, in each direction, 78% of the time is occupied in steaming and 22% in drifting. In making these calculations, it is estimated that an engine steams always at full capacity, shutting off steam entirely when the speed limit is reached, and drifting without steam until the speed is sufficiently reduced. The estimate of time consumed in other ways is based on observation and experience, but any probable error in it will not be large enough seriously to affect any conclusions reached in this paper.

The percentage distribution of time of freight-train locomotives on the road is as follows:

	Through freight.	Way freight.
Working	78	78
Drifting	22	22
Delays at terminals and on account of other trains	65	40
Switching at stations	..	80
Waiting account handling less than carload	..	80
Total	165	300

The average running time between stations, as shown by velocity profiles, was 23.0 miles per hour. The direct freight-train mileage shown on page 359, therefore, required in actual running time:

Through freight	8 762 000 miles	381 000 hours
Way and mixed freight	1 981 360 "	86 000 "

The entire time of these trains, distributed according to the ratios given, was:

Steaming:	Through	381 000 × 0.78	297 200	
	Way	86 000 × 0.78	67 100	364 300
Drifting:	Through	381 000 × 0.22	83 800	
	Way	86 000 × 0.22	18 900	102 700
Delays:	Through	381 000 × 0.65	247 700	
	Way	86 000 × 0.40	34 400	282 100
Switching:	Way	86 000 × 0.80	.....	68 800
Handling less than carload:	Way	86 000 × 0.80	.....	68 800
	Total			886 700

In percentage, this amounts to:

Running:	Steaming	41%	
	Drifting	11.6%	52.6%
Standing:	Delays	31.8%	
	Switching	7.8%	
	Handling less than carload	7.8%	47.4%
	Total		100.0%

The approximate consumption of coal, of 12 000 B. T. U. per lb., by locomotives not working, has been given,* as follows, in pounds per 1 000 sq. ft. of heating surface:

Firing up, per trip	510 lb.
Standing, per hour	121 lb.
Drifting, per hour	219 lb.

* *Bulletin 148*, Am. Eng. Assoc.

On the basis of 2 lb. of coal per hour per sq. ft. of heating surface, when steaming, the consumption while standing was 6% as much, and while drifting 11% as much. The fuel used while switching at stations is estimated at one-half as much per hour as when standing.

The percentages of fuel used in various ways are as given in Table 4.

TABLE 4.

	Percentage Rate:		Percentage of fuel.
	Of time.	Of use of fuel.	
Steaming	41.0	100% = 41.000	84.5
Drifting	11.6	11% = 1.276	2.6
Delays at terminals and account of other trains	31.8	6% = 1.908	3.9
Switching at stations	7.8	50% = 3.900	8.0
Handling less than carload	7.8	6% = 0.468	1.0
Total		48.552	100.0

This account, therefore, is apportioned: Terminal less than carload, 1%; terminal carload, 8%; and resistance 91 per cent.

Water, Lubricants, and Other Supplies.—These expenses are apportioned the same as "Fuel".

88.—Road Trainmen.—These expenses should be apportioned according to the time spent by engines in various operations, except that allowance should be made for part of a train crew being engaged in handling less than carload freight, while the remainder are switching:

Train-miles (running time plus waiting for other trains)	84.4%
Terminal carload (switching)	6.0%
Terminal less than carload	9.6%
Total	100.0%

89.—Train Supplies and Expenses.—All or nearly all these items are car expenses and are variable with the distance that freight is transported. The charge, therefore, belongs to car-miles.

99.—Loss and Damage, Freight.—To the extent that damages occur before freight is actually in transit, or after it has reached the station to which it is destined, they are a terminal expense. The writer estimates this proportion as 60%, of which two-thirds is less than carload. Of the 40% occurring in transit, 60%, is estimated as proportional to train-mileage. The entire account is: Terminal less than carload, 40%; terminal carload, 20%; train-miles, 24%; and car-miles, 16 per cent.

V.—General Expenses

These expenses are apportioned according to the proportions of all other accounts. Table 5 shows the complete analysis of direct freight expenses.

TABLE 5.—ANALYSIS OF DIRECT FREIGHT EXPENSES.

Interest on Investment

Certain parts of the investment in railroad properties increase about in proportion with the increase of traffic. The principal items thus affected are equipment, buildings, yard and individual tracks, and second tracks. Interest on these investments is, therefore, a part of the direct cost, and has been distributed in the same manner as the operating expenses. The average cost of money to the Grand Trunk Railway Company has been estimated at 5%, including discount and commissions.

Equipment.—The investment in equipment was estimated, as follows:

Passenger locomotives	$ 3 736 000
Freight locomotives	10 651 000
Passenger cars	7 357 000
Freight cars	22 575 000

Locomotives.—The interest on investment in passenger locomotives is $186 800, of which, on the basis of passenger train-mileage, 93.5%, or $174 700, was direct. On freight locomotives, the interest was $532 550, of which 97.4%, or $518 700, was direct. This is divided on the basis of road and switching mileage, the same as locomotive repairs.

Passenger Cars.—Interest on this investment is $367 850, all direct.

Freight Cars.—The interest on this investment is $1 128 750, all direct, and is divided on the basis of time consumed in loading and unloading as compared with that in transit, which has been estimated as 60% and 40%, respectively. The amount, therefore, is apportioned as follows, terminal carload 60%, and car-mile, 40 per cent.

Buildings.—It was estimated that the investment in buildings was $17 000 000, and that the buildings were used to 90% of their capacity. The interest, therefore, was $850 000, of which $765 000 was direct. This is apportioned the same as the maintenance of buildings, fixtures, and grounds.

Yard Tracks and Industrial Sidings.—The investment in these tracks is estimated as 996 miles at $8 000 per mile, or roughly as $8 000 000, the interest on which would be $400 000. On the basis of locomotive switching, 90% belongs to freight. It has been shown that 217 miles of 996, or 22%, were used in through service. This percentage of the interest, therefore, is charged to distance, as a car-mile expense, and the remainder to terminal carload.

Second Tracks.—The Grand Trunk Railway Company has 707 miles of second track, but it appears that the greater part of this investment was not made necessary by the growth of traffic, and the inclusion of interest thereon as a direct charge on operations, therefore, would cause the relation of cost of service to growth of traffic to be incorrectly represented.

Hire of Equipment.—This item may properly be included with interest, as a charge of the same nature. The amount, $554 000, in the absence of records by which it could be directly assigned, has been divided between freight and passenger in the same ratio as the investment in cars, namely, 75% freight, 25% passenger, and the former has been apportioned in the same manner as interest on freight cars.

Indirect Interest.—In this study, as presented to the Board of Arbitration, only interest actually paid was considered, no account being taken of investment represented by stock. In order that the true relation between direct and indirect costs may be shown, the entire investment must be considered, as interest, or return on it, is as much a part of the cost of service as the operating expenses.

The books of the Grand Trunk Railway Company show on December 31, 1913, an investment in road and equipment of $380 000 000, or $122 000 per mile. Much of the property of the Grand Trunk was acquired in exchange for stock, so that the figures given do not represent the true investment. An approximate estimate is sufficient for the purpose of this paper, and, therefore, it has been taken at $250 000 000, or $80 000 per mile. The investment already assigned amounts to $70 000 000. The interest on the remainder is $9 000 000, which is divided between freight and passenger service in accordance with the sum of all direct costs, namely, freight, 73%, and passenger, 27 per cent. The results of the analysis of interest appear in Tables 6 and 7.

Taxes.—Taxes, amounting to about $475 000 per year, are an indirect cost and are apportioned on the same basis as indirect interest, namely, $347 000 to freight and $128 000 to passenger service.

Table 8 summarizes the cost of service. A comparison of earnings with cost in each service shows the passenger service to have been the more profitable. In 1913, freight revenues were $27 930 000, and passenger revenues, $14 280 000. The direct cost of freight service was 75% of the revenue, and that of passenger service was 55 per cent. Compared with the entire cost, the percentages were 110% for freight and 83% for passenger service.

Train-mile costs are shown to have been only about 60% as much as car-mile costs. A reduction of car-miles by heavier loading, therefore, will do more to effect economy than hauling more cars per train. The largest field for saving is in terminal operations which cost more than train-miles and car-miles combined. The direct cost was twice as much as the indirect cost.

Unit Costs

The direct cost of each unit of operation is next to be determined.

Terminal Less Than Carload.—The records of the Grand Trunk Railway Company afford no basis for estimating less than carload tonnage, but a similar analysis of cost of service of the Grand Trunk Western Railway Company gave 85 cents per ton for less than carload and one of the Atlantic and St. Lawrence Railway Company gave 80 cents per ton.

Terminal Carload.—The series of movements by which a car of freight is handled terminally has been classified, as follows:

At Point of Origin:

1.—Empty car from yard to shipper.
2.—Loaded car from shipper to yard.
3.—Loaded car from yard to train.

At Destination:

4.—Loaded car, train to yard.
5.—Loaded car, yard to consignee.

6.—Empty car, consignee to yard.

7.—Empty car, yard to train (for return).

At Point of Origin:

8.—Empty car, train to yard.

All these operations are considered as equal in cost, and the sum of them is taken as the number of units of terminal carload operation. This apportionment is based on handling by yard crews, but practically the same work is done at other points by road engines. The cost of maintenance of all tracks and equipment, all accounting work, and the various switching movements not directly assignable to any of the operations previously mentioned, are considered as spread uniformly over them.

In computing the number of these movements, the writer has considered interchange of traffic with the lines of the Grand Trunk Railway Company in the United States as not equivalent to terminal handling, but to movement through division points, which is a car-mile expense. The total tonnage handled is classified as follows, the number of cars being calculated at the ratio of 18.18 tons per car, the average loading of loaded cars at that time:

	Tons.	Cars.
Local Tonnage:		
Originated	6 732 000	370 400
Delivered to consignee	11 980 000	659 000
Interchange:		
Received from carriers	8 979 000	493 900
Delivered to carriers	4 886 000	268 700
Totals	32 577 000	1 792 000

Each car of local tonnage originated required the first three movements designated previously, or $3 \times 370\,400 = 1\,111\,200$ unit terminal movements. Each such car delivered required the fourth to sixth movements, or, $3 \times 659\,000 = 1\,977\,000$ units.

In interchange, the connecting road takes the place of the shipper or consignee, but there is no empty car to be placed or taken away. Each interchange, therefore, required two unit movements instead of three, making 1 525 200 units.

In 1913, empty car-miles amounted to 85 000 000. The average haul of loads was 178 miles, and this has been taken as the distance moved by each empty car. There were then 477 500 empty cars moved, each of which required the seventh and eighth movements, making 955 000 unit movements. The total was 5 568 400 unit movements.

The direct cost is shown by Table 8 to have been $3 901 252, or 70 cents per unit for operating expenses, and $1 387 850, or 25 cents per unit for interest, a total of 95 cents per unit of terminal handling.

Distance.—Train-Miles.—The operations of the Grand Trunk Railway Company for 1913 required 10 743 360 direct freight train-miles, at a cost for expenses peculiar to train movements of $2 520 920, or 23.5 cents per train-mile, practically all operating expenses.

Distance.—Car-Miles.—The freight car-miles amounted to 300 331 000, at a cost of $3 325 983, or 1.11 cents per car-mile, for operating expenses, and $834 100, or 0.28 cents for interest, a total of 1.39 cents per car-mile.

Distance.—Gross Ton-Miles.—There were 8 440 727 000 gross ton-miles produced at a cost of $817 200, or 9.7 cents per 1 000 ton-miles, practically all for operating expenses.

Resistance.—The unit of Resistance is that of lifting 1 ton 1 ft., or of 1 ft-ton. The results of the experiments at the University of Illinois have been used in making velocity profiles. Calculations based on an assumed average weight of 35 tons per car, have been made showing the resistance necessary to be overcome in moving a train over each district of the System, making due allowance for acceleration, speed, grades, curvature, and stops, and tables have been prepared giving the foot-tons of work actually done in moving freight on the railroad during the period under consideration. The total resistance overcome was 275 454 000 000 ft-tons. The cost was $5 820 060, or 2.11 cents per 1 000 ft-tons for operating expenses, and $562 400, or 0.2 cents per 1 000 ft-tons for interest, a total of 2.31 cents per 1 000 ft-tons.

Indirect Cost.—About 8.5% of the direct cost is apportioned to terminal handling of less than carload freight. The same proportion of the indirect (freight) cost, or $830 000, therefore, is assigned to less than carload freight. About 25% of the direct cost is assigned to terminal carloads, which is independent of the distance freight is moved. The writer, therefore, apportioned 25% of the indirect cost, or $2 460 000, on the basis of tons handled terminally. This equals 7.5 cents per ton of carload freight. The remainder, $6 350 665, is apportioned on the basis of net ton-miles, amounting to 0.17 cent per ton-mile.

Similar analyses were made of the operations of the Grand Trunk Western Railway and the Atlantic and St. Lawrence Railway. The unit costs of all three roads were found to be as given in Table 9.

TABLE 9.

The details making up each unit cost for the Grand Trunk Railway Company are given in Table 10.

Operating Conditions

The first step in the application of unit costs is the determination of the exact conditions of train and car loading under which traffic was moved. In applying the results of the calculations of resistance to cars of weights other

than the average of 35 tons, allowance must be made for the corresponding difference in frictional resistance. The correction does not apply on descending grades exceeding about 0.3%, as the resistance is then overcome by gravity.

Empty-Car Movement.—On all districts of the Grand Trunk Railway, there is throughout the year a preponderance of traffic eastbound. There is a large empty-car movement westward and a small one eastward. The cost of each belongs to the freight moved in the opposite direction. Where the traffic is of special character, requiring the return west, empty, of each car sent east, the calculation of cost is made accordingly. Otherwise, each loaded car east is charged with a fraction of an empty car west according to the ratio of empties to loads. The train-mile and car-mile costs of empty-car movements are the same as for loads. The gross ton-mile cost varies with the weight. The resistance cost is the same per foot-ton, but the resistance varies with the weight of the car.

Train Loading.—It is assumed that the ratio of car-miles to train-miles eastbound on each division represented the normal train loading for that division. The loaded car-miles westbound were divided by this ratio, in order to

obtain the train-miles required to move west bound freight. The remaining actual train-miles west were considered as belonging to the empty movement, and the number of empties per train was determined accordingly. It is true that loaded and empties moving westward are not separated in the manner described, but it appears to be improper to charge to the cost of west bound freight any expense arising from its being mixed with empties hauled west in order to carry freight east.

Application of Unit Costs

The cost per car for a given freight movement is equal to the sum of the following:

The terminal carload cost per car, at each end of the movement.

The train-mile unit cost, multiplied by the distance moved, and divided by the number of cars per train.

The car-mile unit cost, multiplied by the distance moved.

The gross ton-mile unit cost, multiplied by the distance moved, and by the number of gross tons per car.

The resistance cost per foot-ton, multiplied by the number of foot-tons resistance per ton, and by the gross weight of the car, plus a proportionate part of the weight of the engine and the caboose.

Charge for empty-car movement in opposite direction, if any.

Table 11 shows the application of the unit costs to the movement of a car of dressed meats from Chicago to Portland, Me. The average load carried was 10 tons, with 3 tons of ice, making the gross weight 38 tons. The number of cars and of gross tons per train on each district were taken from tables compiled for the purpose from statistical records of the Grand Trunk Railway. The equivalent rise in feet, under resistance, was taken from velocity profiles, corrected for a 38-ton car.

The terminal cost at Elsdon, Ill., is the unit cost of the Grand Trunk Western Railway multiplied by three, and covers the movements required to place the car in a train ready to leave the Elsdon Yard. This cost is assumed to be the same at all stations on the railroad. Probably some modifications should be made for special conditions at Elsdon, but this was not done, for the effect would be relatively small on so long a haul, and the exact conditions were not known. At Deering, Me., the rates of the Atlantic and St. Lawrence Railway Company were used.

The length of each district, divided by the number of cars per train, gives the number of train-miles, the cost of which must be borne by each car. The total tons under resistance equal the weight of the car, 38 tons, plus a proportionate part of the weight of the engine and tender, taken as 145 tons. Cars are handled from the stockyards to Elsdon, from Mimico, Ont., through Toronto, to York, Ont., Canada, and from Deering to Portland, Me., by yard engines, and the cost is included in yard expenses.

Certain corrections must be made if cars are owned by the shipper. Charges for freight-car repairs, train supplies, interest on freight cars, and

hire of equipment, as far as it has been applied to cars at an average rate, must be eliminated.

Another correction is to be made because dressed meats move in manifest, or fast freight, trains, which are made up so as to require less handling in yards than other trains; therefore, the charge for yard expenses, under car-mile costs, must be reduced for this class of business. The charge is estimated by the writer at one-fourth as much as for ordinary through freight, and the manifest is estimated as one-fourth the total through movement. Locomotive repairs would be similarly affected, as all this expense which is charged to car-mile costs is on account of through cars in yards. Of freight-car repairs, about one-half come from the same cause, and would be affected in the same ratio. The results of these corrections are shown in Table 11.

Additions to the calculations mentioned are made because of rentals paid for the use of privately owned cars, 1 cent per mile, whether loaded or empty, and for passage through the St. Clair Tunnel, $1 for the loaded car and 50 cents for the empty.

An empty car hauled in the same train, would have one-third as much for terminal cost, and the same cost for train-miles and car-miles. The gross ton-miles would be proportional to the weight of the car. The "total tons", under resistance, would also be proportionately reduced, but the resistance per ton would be about 50% more for the light car. The total cost would be about 80% as much as for the load. The cost of the return of the empty refrigerator car to Chicago was calculated at $50.40, the more than average weight of the car and the charge for rent bringing the cost, in this case, to 90% of that of the load.

The full cost of the return must be charged to the east bound freight because nothing was moving west for which this type of equipment was suitable. In a similar calculation for a commodity moving in general purpose cars, there should be included only that fraction of the cost of the empty car represented by the ratio of the empty cars west to the loads east. If, however, the question, instead of being one of distribution of costs among kinds of business already existing, was one of the cost of taking on additional traffic eastward, it would be proper to charge against it the entire cost of the empty-car movement west. On the other hand, additional traffic westward would not only have no empty movement against it, but the additional cost would be only the difference between the cost of moving a load and that of an empty, which would be small, as shown previously.

The indirect cost has not been computed for the Grand Trunk Western and the Atlantic and St. Lawrence Railways, owing to the difficulty of determining the investment in these subsidiary companies, but it may be taken as the same as that of the Grand Trunk Railway. The amount assigned to each ton of the freight under consideration would be:

1 ton at Elsdon, Ill.	$0.075
1 121 ton-miles @ $0 017	1.900
1 ton at Deering, Me.	0.075
Total	$2.050

The application of unit costs thus ascertained will always require care in allowing for the special conditions surrounding each case, but the writer believes that it will be found practicable to apportion costs of handling various commodities with an accuracy comparable to that of a manufacturer calculating the cost of the various products of his factory. Discussion is needed as to the principles set forth and the ratios used herein, in order that a wider range of experience and judgment may be brought to bear on them.

In the preparation of this analysis, other members of the Arbitration Staff of the Grand Trunk Railway Company were consulted repeatedly. Valuable assistance was rendered by Messrs. R. A. C. Henry, Engineer in Charge, and M. A. Fullington and F. W. Cooper, Division Engineers. Messrs. George O. Somers, Traffic Expert, and A. D. Porter, Mechanical Engineer, furnished much useful information. Mr. V. I. Smart and E. W. Moreland, Assoc. M. Am. Soc. C. E., who were assigned as Assistants on the work, were invaluable in assembling material and in the solution of the many problems which arose. The criticisms of J. G. Sullivan, M. Am. Soc. C. E., on the completed work caused much of it to be revised, and, it is believed, to be greatly improved.

The science of railroading covers too wide a field for any one man to be expert in every part of it. The writer was especially fortunate in having the advice and assistance of so many men of wide experience and ripe judgment. If the results prove useful in the solution of railroad problems, a large share of the credit will be due to these men.

DISCUSSION

J. G. SULLIVAN,* M. AM. SOC. C. E. (by letter).—The author is deserving of the gratitude of railway engineers for bringing this important subject before the public. There is every reason why railroad men should know what transportation is really costing, and, further, the students of the economics of railway location will be well advised in giving this paper very careful study, although they may not agree with all the methods and the indicated conclusions.

In general, the writer's criticisms of the paper resulted in decreasing the ratio of the direct charges to the total.

The reason for this further discussion is that the writer believes that in reading Mr. Newell's paper those who are not familiar with railway operation may arrive at a false conclusion, namely, that, in general, passenger business is more profitable than freight business.

It is not thought that Mr. Newell intended to give that impression, but the writer's experience has been that there are certain classes always ready to grasp at straws to further their arguments as to why passenger rates should be lowered.

In 1894, the writer listened to a member of the "Coxey Army" haranguing a crowd in St. Paul, Minn., whose grievance was high passenger rates. He quoted the cost per 100 lb. weight for carrying a hog from St. Paul to Chicago, and compared this rate with the fare he would have been charged by the railway. One can readily see now such a man would take undue advantage of any figures that might tend to prove his case, especially if he were a member of a legislative body.

The writer cannot agree with the author's conclusion that "passenger service was more profitable than freight", even in the particular case under consideration. The passenger business on the Grand Trunk Railway was the "star boarder", as it is in all railways. The track has to be kept in shape for that particular business. Extra side-tracks of extra lengths must be built so that the freight business can be kept entirely out of the way of its more favored rival. If these facts are not taken into consideration, then, in the writer's opinion, the conclusions are not reliable.

A few of these adverse factors that increase the cost of freight service may be mentioned in the following questions:

(1) If a road had no passenger service, how much could it reduce the first cost and interest of locomotives and cars on account of being able to make better time?

(2) How much could the number and length of passing sidings be reduced, if there was no passenger service? (A double-track railway would practically require none.)

(3) It is true that Mr. Newell loads the passenger traffic in computing the cost of maintenance-of-way charges, but how many railway engineers will admit that this loading more than compensates for the actual damage done

* Cons. Engr., Winnipeg, Man., Canada.

due to speed, leaving nothing to compensate for keeping the roadway in a condition far better than the economics of freight service would warrant.

(4) How much of the fuel used in stopping and starting freight trains and burned while standing in side-tracks waiting for passenger trains to meet or pass, should be charged to passenger service?

(5) How much of the extra time of train crews and engine crews in freight service, as mentioned in Factor (4), should be charged to passenger service?

(6) Even if it is taken for granted that Mr. Newell's figures for the ratio of direct charges are correct, is he justified in dividing taxes, interest, and general expenses in the same ratio?

Most business concerns will compare the direct charges with the revenue from a certain line and then decide whether or not it is profitable to continue that line. One might get the impression from the author's statement that, "compared with the entire cost, the percentages were 110% for freight and 83% for passenger", that it would be advisable for the Grand Trunk Railway Company to go out of the freight business; such a conclusion, of course, would be absurd. If Mr. Newell had divided what he calculated as indirect interest, taxes, and general expenses on the basis of revenue received, the result would have been 107% for freight service and 90% for passenger service. If these items had been divided "fifty-fifty", the result would have been. 101% for freight service and 100% for passenger service.

The writer does not suggest that these latter divisions are more logical than those used by Mr. Newell, but simply uses them to show what very different results one may obtain, depending on the point of view that suggests the assumptions.

Another feature that supports the writer's views is the fact that although it would have been to the interest of the Government to establish Mr. Newell's conclusion, the solicitors did not feature this conclusion.

The writer wishes in no way to detract from Mr. Newell's excellent paper other than to prevent those who may not be familiar with railway operation making a mistake by drawing false conclusions.

J. P. Newell,* M. Am. Soc. C. E. (by letter).—The question raised by Mr. Sullivan in regard to the apportionment of the indirect expenses between freight and passenger service is one which confronts the student in every allocation of costs of production. These expenses would exist to the same extent if the operations of the road were confined entirely to either service. If the problem was the advisability of abandoning one branch of service, the passenger service, for example, it would then be proper to charge the entire amount of indirect cost to freight service, with the result that passenger business would appear to be tremendously profitable. In like manner, a large profit could be shown for freight service by assuming that the primary function of a railroad is to carry passengers, and charging all indirect costs to that service.

The writer has assumed that it is the business of a railroad to carry both freight and passengers and that neither should have any preference in alloca-

* Cons. Engr., Portland, Ore.

tion of charges. It is necessary, therefore, to find some equitable basis for apportioning those costs which are not dependent on either the volume or the character of the traffic carried. Just what that basis should be, it is not easy to determine. Apportionment according to the respective revenues at once suggests itself. This method, however, is correct only if freight and passenger charges are adjusted properly with reference to each other. The writer has not been able to find any more equitable basis than that which he has used.

In the matter of direct costs, only the maintenance-of-way charges offer any serious difficulty in allocation. Even if the clearly unreasonable proportion of 75% of these expenses on the Grand Trunk Railway in 1913 was charged to passenger service, such service would still show a slight gain, and freight, a loss. It appears, therefore, to the writer, that although there is much room for difference of opinion as to the exact method of distributing costs between freight and passenger service, the latter was the more profitable in that year. Since then, however, the comparative falling off in Grand Trunk passenger traffic has undoubtedly changed this relation.

PROGRESS IN HIGHWAY RESEARCH

By W. K. Hatt,* M. Am. Soc. C. E.

It appears that an early solution of the more complicated problems, and, from the standpoint of National well-being, the graver problems of highway transport, will be reached only in so far as the highway engineer, the highway official, the vehicle designer and manufacturer, and the organizer and operator of highway transport systems, in conference, can come to an understanding of the aims of each, and to a recognition of the public service to which they are called. To this group should also be added, steam and electric railway operators, so that highway transport may find its appropriate function in a co-ordinated structure of National transportation.

Highway engineers and motor vehicle manufacturers are now seeking a common viewpoint, and are in the way of finding a common purpose from which to reach sound policies in the financing, building, and the use of highways. It is hoped that the contribution of those representing other systems of transportation to a scientific study of these questions may be had.

Co-Ordination of Research.—The Advisory Board on Highway Research, Division of Engineering, National Research Council, is organized to prepare a comprehensive National program for highway research; to assist existing organizations to co-ordinate their activities therein; and to collect and distribute information of completed and current research. This is not a directing, but a service, organization, devoted to the interest of the individual researcher. Services that can be rendered the individual researcher are in soliciting support for his projects, in putting him in touch with his fellow workers through a Census of Research, and in illuminating a particular field with sidelights from allied fields in which a project has its setting. The taxpayer will also benefit through a co-ordinated research activity on problems selected from a comprehensive program with reference to the applicability to present-day problems.

For example, highway researches in the field of economics of operation are connected under Committee No. 1 on the Economic Theory of Highway Improvement, T. R. Agg, M. Am. Soc. C. E., Chairman. In New England, the tractive resistance of automobiles and trucks is being measured on several types of roads at speeds up to 30 miles per hour. The vehicles are tested for internal absorption of energy at the Yale Laboratory by Professor E. H. Lockwood, and the gross tractive resistance determined on the roads by Maj. Mark L. Ireland, Q. M. C., U. S. A., who is stationed at the Massachusetts Institute of Technology. Co-operating in this work are: The Bureau of Public Roads, U. S. Department of Agriculture, the Committee on Economic Theory of Highway Improvement, National Research Council, the Connecticut Highway Commission, the Department of Public Works, Commonwealth of Massachusetts, Harvard University, the Massachusetts Institute of Technology, the Society of Automotive Engineers, the United States Army, Quartermaster Corps, and Yale University.

* Director, Highway Research Committee, Div. of Eng., National Research Council, Washington, D. C.

The investigation includes the effect on tractive resistance of the temperature of the differential of the vehicle, and of various types of tires. The gross tractive resistance is composed of several elements, such as engine, gearing, inelastic resistance of body, tire, windage, road surface, which distinguishes rolling, impact, and displacement resistance. Account must be taken of the absorption and giving out of energy in the rotating parts, in accelerating or retarding speed. The technique of these measurements is not settled. The measuring instrument may be an accelerometer used in coasting tests, or a dynamometer used in towing tests, each of which has its peculiar advantages. The first task is to determine the best instrument to measure the several elements into which the problem is analyzed. The Bureau of Standards has assembled apparatus which automatically records the measurements of about fourteen elements of car performance in road tests.

L. E. Conrad, M. Am. Soc. C. E., at Manhattan, Kans., is conducting a parallel investigation of the resistance of the air to the passage of vehicles.

At the University of Michigan, Professor Lay in a study of economic grades has towed four Packard trucks over gravel and concrete roads, after he had determined their characteristics in the laboratory. The gravel roads varied in condition from wind-swept hard surfaces to a loose gravel surface. The concrete road varied from a smooth finish to a somewhat wavy condition. The gasoline consumption was also reported. The trucks were 5 ton, with 3-ton pay load, and were operated at a standard engine speed of 1 000 rev. per min., the gears being shifted to meet road conditions. Professor Lay finds that, for these trucks, the tractive resistance, including rolling resistance, tire resistance, and windage, varied from 40 to 44 lb. per ton on the gravel roads, and from 22 to 26 lb. per ton on the concrete roads, all at a speed of 10 miles per hour.

At Ames, Iowa, Professor Agg has been investigating the economics of highway location and operation, especially with a view to determining economic grades.

The end in view is a sound economic theory of highway location and improvement. Each of these investigations forms part of a whole. The individual researches profit by intercommunication, and, in the end, the entire results are more likely to be useful in the formation of principles by a co-ordinating service.

In the field of design may be mentioned the experimental road at Pittsburg, Calif., and the Bates test road near Springfield, Ill., investigations of A. T. Goldbeck, Assoc. M. Am. Soc. C. E., of the U. S. Bureau of Roads, and the service test roads at Byberry and Lancaster, Pa., Casper, Wyo., Alexandria County, Virginia, Wilmington, Del., and Milwaukee, Wis. These tests are directed to the same end and will supply co-ordinated data through the Committee on Design; they will place the mechanics of slab design on a scientific basis.

In the field of highway transport, the pioneer transport surveys on the Connecticut roads, started by Charles J. Bennett, M. Am. Soc. C. E., State Highway Commissioner, have crystallized former vague discussions, and have stimulated further work. The examinations by A. N. Johnson, M. Am. Soc. C. E.,

of the University of Maryland, by N. W. Dougherty, M. Am. Soc. C. E., of the University of Tennessee, by Professor Agg in Iowa, by the Bureau of Public Roads in California, and less complete traffic counts in scores of instances—all these need to be reported and examined for fundamental laws of traffic by a Committee on Traffic Analysis.

A useful and money-saving activity is in the Research Information Service of the Advisory Board, by which a State is informed of the findings from investigations in another State. Cases can be cited in which one State has been saved the delay and cost of an investigation relating to the use of materials, when informed of the completed investigation available from the work of another State. The recent tabulation of the incomplete returns of the Highway Research Census of the Advisory Board indicates not only great activity in this field in the 430 projects, but the possibilities of economy in time and money and the avoidance of unnecessary duplication. Table 1 gives the number of individual research projects in highway engineering and highway transport.

TABLE 1.

	Economics.	Operation.	Design (road).	Construction.	Materials.	Total.
Colleges and universities	17	3	47	12	127	206
Industrial	1	1	3	0	19	24
Municipalities	5	1	6	1	18	31
State highway departments	13	2	25	8	101	149
State geologists	0	0	3	0	17	20
Total	36	7	84	21	282	430

It must be said, however, that duplication is not necessarily an evil; indeed, it is useful in fundamental matters, as in the case of the investigation of fatigue of concrete. The parallel investigations at Springfield, Ill., Purdue University, and the University of Maryland, with different methods of attack, will more certainly lead to the truth. However, in these cases, each will profit by communication with the other.

H. S. Mattimore, Assoc. M. Am. Soc. C. E., Engineer of Tests, State Highway Department, Harrisburg, Pa., is Chairman of the Committee of the Advisory Board on the Character and Use of Road Materials; he is also Chairman of the Committee of Tests and Investigations of the American Association of State Highway Officials. The latter Committee is divided into sub-committees, each representing a region of the United States. Mr. Mattimore is furnished by the Advisory Board with an administrative assistant, and this combined attack on problems relating to the materials of construction represents a well-organized committee activity.

These few instances will serve to demonstrate the value of the services of the Advisory Board in combining individual researches.

POLLUTION OF STREAMS BY PULP-MILL WASTES

By George C. Whipple,* M. Am. Soc. C. E.

The manufacture of wood pulp is a hydro-chemical process; consequently, pulp mills are always located on streams or canals. Large volumes of water are required and the waste waters which contain the spent chemicals and the washings of the pulp, pollute the streams. Whether this pollution does damage down stream depends on many factors, namely, the relative volumes of waste and of stream flow and the variations in flow; the quality of the river water and the character of the wastes; the opportunity for mixing, the velocity of the current, the existence of riffles, slack water, aqueous vegetation, re-aeration, sedimentation, and the many factors which bring about the natural purification of streams; and, finally, the use which is made of the river water down stream. These factors are common to all forms of stream pollution resulting from hydro-chemical processes, but there are no two places where the conditions are exactly alike. Every polluted stream has its own set of conditions, therefore, generalizations are hazardous. The speaker will only call attention to certain facts regarding pulp-mill wastes and discuss briefly the larger problem of stream pollution by industrial wastes.

It should be noted that the pollution of streams by pulp-mill wastes is only a part of a more general problem—the pollution of streams by trees and tree products—a problem which appears in many forms. Annually, the leaves fall, decay, and the products of their leaching are carried into ponds, brooks, and rivers. Trees die and gradually their wood decomposes. Trees are floated down stream to the mills, and their soakage tends to increase the color of river water, although the effect is not great. Logs are sawed; the saw-dust lies in heaps or washes into the rivers and the pollution takes a different form. All these processes are slow, and the resulting pollutions are regarded as natural. It is only when wood fiber is treated chemically, when vast quantities of logs are brought to one mill, that stream pollution becomes a problem. Pulp-mill pollution is also akin to that of strawboard waste pollution and to beet-sugar pollution, both of which involve the decomposition or chemical treatment of vegetable fiber and the use of water in large quantities.

There are three processes of making wood pulp, which need to be distinguished from each other because of the difference in their waste products. They may be referred to as (*a*) ground pulp; (*b*) soda pulp; and (*c*) sulphite pulp. The object of all these processes is to separate the fibrous from the non-fibrous parts of the wood, the fibrous materials being used for making paper.

Ground pulp is made by cutting logs into short lengths and pressing them against rough grinding wheels kept wet with water. The resulting crude pulp is washed, screened, deposited as a blanket, rolled, and dried. Mechanical pulp thus prepared contains not only cellulose but also lignin and resinous matter. The wash water contains a large quantity of wood fiber and extractive matter, sometimes 10% of the weight of the wood. Chemically, it resembles saw-dust, but is finely shredded instead of granulated.

* Cons. Engr.; Prof., San. Eng., Harvard Univ., Cambridge, Mass.

In the soda process, soft wood, usually poplar, is chipped and digested in hot caustic soda, the resulting pulp being washed, bleached, drained, and worked into the usual blanket form. Soda digestion yields a soft grayish-brown pulp and a black liquor which results from the decomposition of the lignin and resins. A large part of the soda used is recovered by concentrating this black liquor in evaporators, burning off the lignin and other organic materials in rotary furnaces, leaving carbon and sodium carbonate which is leached out and converted back to caustic soda by boiling with caustic lime. As a result, there is wasted a small volume of black-ash sludge which contains a little unleached soda ash, and a large volume of calcium carbonate sludge. A small volume of lime sludge resulting from the bleaching process is also wasted. The liquid wastes consist of wash waters from several parts of the process. They contain wood pulp, caustic soda, and hypochlorites, but are usually not large in volume. In recent years, electrolytic methods of producing caustic soda and calcium hypochlorite from brine have been introduced and savings made which have reduced the waste products. It is said, however, that for every ton of wood-pulp product about 150 lb. of caustic soda are lost.

If all the solid waste products from soda pulp mills were to be discharged into the streams, a serious pollution would occur. Sedimentation basins are usually provided and with them it is possible to retain the bulk of the sludge. The volume of the sludge is very large, however, and in the course of years large areas are required. Unless the sedimentation beds are well operated, foul liquids are likely to be discharged from them, either by drainage or by overflow at times of rain. On the whole, however, the soda process, with its recovery methods, destroys a large part of the lignins and wood extractives by burning, and the pollution of streams by soda pulp mills is more a mineral than an organic pollution.

In the sulphite process, the wood fiber is disintegrated by the use of the sulphites of calcium and magnesium with an excess of free sulphurous acid. Spruce and hemlock are the woods commonly used. The sulphite is manufactured by passing sulphurous acid through a suspension of milk of lime, or by burning sulphur and passing the fumes into an acid tower packed with crushed limestone or dolomite, water being allowed to trickle down as the fumes ascend. The sulphite solution runs out at the bottom of the tower and is pumped to the digesters in which the chipped wood is packed. After digestion for several hours under high pressure, the contents are delivered into a pit from which the waste liquor drains off, leaving the fiber. This waste sulphite liquor has the appearance of a thin molasses, and has a woody, acrid, sulphurous odor. It often contains as much as 10% of solid matter, consisting of wood fiber, lignin, resin, and wood extractives modified by the process. It generally contains sulphurous acid, sometimes as much as 0.5 to 1 per cent. The pulp is screened, washed, and perhaps bleached, and is worked into a blanket ready for paper-making, these processes yielding waste waters which contain fiber and other impurities. It will be observed that in the sulphite process the lignin, resin, and wood extractives are wasted to the stream, whereas, in the soda process, they are mostly burned. For this reason, the pollution of streams

by sulphite pulp mills has proved a more serious matter than that caused by pulp mills using the soda or the mechanical process.

The volume of the liquid waste from a sulphite pulp mill is large and may be as much as 800 to 1 000 gal. per ton of pulp. It is said that for each ton of finished pulp an equal quantity of organic material is discharged into the stream as waste liquor, together with about 400 lb. of sulphur in acid form or organic combination. The action of the bisulphites on the lignin is to produce a mixture of sulphonated substances which give rise to lignin-sulphonic acid or the calcium or magnesium salts of this organic acid.

Earle B. Phelps, Affiliate, Am. Soc. C. E., has given the following average analysis of two samples of sulphite liquor, which may be regarded as typical:

	Parts per million.
Total solids	95 000
Loss on ignition (organic)	82 000
Oxygen consumed	36 000
Ash (mineral)	13 000
Analysis of ash:	
Calcium (Ca)	2 200
Magnesium (Mg)	1 200
Sulphur (S)	2 000
Free SO_2	1 000
Total sulphur (mineral and organic)	10 500

Mr. Melville C. Whipple, who analyzed a sample of the waste sulphite liquor at one of the mills on the Black River, New York, found that it had an iodine absorption equivalent to 224 parts per million of SO_2.

As far as the speaker is informed, no successful method of utilizing or treating sulphite wastes has yet been devised. Its acid condition precludes the use of bacterial methods without prior neutralization and its large quantity of soluble matter makes settling processes of little avail. Evaporation, which is an expensive process, seems to be a necessary preliminary to any method of utilization. The use of detention tanks for equalizing the discharge instead of allowing heavy discharges to occur at intervals, is of some benefit but does not solve the problem. If one considers the damage done and also the value of the substances wasted, it is evident that the prevention of pollution by pulp-mill wastes is worthy of careful study by chemical engineers. Sutermeister states that, in Europe, mills have been obliged to close, because it has been impossible to purify the waste liquors sufficiently to comply with legal requirements. Attempts have been made to use the sulphite liquor as a road binder, a binder for moulding sands, a binder for powdered coal, a fertilizer, a sizing for paper, a food for cattle, a source of dye-stuffs, a material for insulation and artificial leather, or a source of alcohol. The speaker has no practical suggestions to make at this time on the utilization and treatment of wastes but, instead, will discuss briefly the effect of sulphite wastes on streams.

The peculiar character of waste sulphite liquor is its sulphur content, its acidity, and its high organic content. Sulphite mills and often the villages in which they are located, reek with the characteristic odor. Sulphurous acid

escapes into the air in such quantities that the water supply, used for process purposes, when exposed to the air, absorbs it, the natural alkalinity of the water being reduced by measurable amounts. Sulphur in other forms may also be absorbed by the process water, partly from the air, but even more from the pulp during the washing processes. One consequence of this is, that the troughs and channels and even the screens and wash-boxes in a pulp mill become coated with slime which is shown by the microscope to consist of *Beggiotoa, Sphærotilus, Leptomitus,* and other fungi which require sulphur for their growth. The slime problem is often serious in pulp mills and frequent shut-downs for cleaning purposes are required. The slime becomes dislodged from the troughs and settles on the pulp blankets, making dirty spots which affect the sale of the product and sometimes require the pulp to be re-washed. A few years ago, at one of the Canadian pulp mills, the speaker experimented on the control of slime growths by the use of copper sulphate coupled with other chemical treatments, but this experimental work had to be given up on account of the World War. Sufficient was accomplished, however, to warrant the statement that the slime growth can be controlled by proper treatment.

It is a fact which is more than a mere coincidence, that these three filamentous fungi, *Sphærotilus, Beggiotoa,* and *Leptomitus,* found in the water of pulp mills, are also found in sewage polluted waters. Together with *Thiotrix* and, perhaps, *Saprolegnia,* they appear to require sulphur and, either by choice or effect, are found in waters of low dissolved oxygen content. These fungi are often found on sticks and stones in the streams below sulphite mills, appearing as clumps or tufts of fibers, sometimes white like cotton, but more often cream-colored, gray, or salmon pink. When they decay, they blacken and become foul smelling, a condition usually associated with septicity, that is, with lack of oxygen and bacterial decomposition.

Deposits of pulp sometimes occur below sulphite mills where there is slack water. The shores often become covered not only with the fungi mentioned, but with growths of *Oscillaria,* the long bluish-green filaments of which enmesh the pulp. In the sunlight, bubbles of oxygen are generated, which also become enmeshed and float great masses to the surface of the water. Various animal forms take shelter in these oxygenated masses, and other algæ grow on them until they become great centers of microscopic life. If there are other pulp or paper mills down stream, the quality of the water at the lower mills is likely to be seriously impaired for washing purposes. These growths can be kept down by the proper application of copper sulphate.

The practical effect of discharging sulphite wastes into rivers depends on the various factors already mentioned. One effect is to make the stream unsightly by reason of deposits of pulp and fungi and the algæ growths previously mentioned, and if a stream once becomes foul in this way, it tends to become a catch-all for many kinds of débris and filth. Uncleanliness is contagious. M. O. Leighton, M. Am. Soc. C. E.,* described the effect of the pollution of Ausable River with sulphite wastes for a distance of twenty miles, and even

* "On the Pollution of Lake Champlain", *Water Supply and Irrigation Paper No. 121,* U. S. Geological Survey, 1905.

into Lake Champlain. He also described the pollution of Bouquet River with soda pulp wastes. Some thought at one time that it increased the algæ growths in the lake, but this was never definitely proved. Phelps* has also written on the general subject of sulphite pulp wastes and has described processes and proposed methods of treatment.

Pulp-waste pollution tends to drive away fish. The fine pulp gets into their gills and the sulphite pollution may kill them by exhausting the dissolved oxygen. The New York Conservation Commission has recently assembled data showing the tolerance of certain fish to industrial wastes and among them are the following: Bass, perch, and trout were killed in about 1 day by sulphite wastes diluted 10 to 1 and when diluted 75 or 100 to 1 trout fry and bass were killed in several days. Dilutions of 100, 200, and 500 to 1 did not kill perch in several days. That death was due to suffocation rather than poisoning was indicated by the fact that a 50 to 1 dilution of the sulphite liquor artificially aerated did not kill perch or bass in 29 days. Bleach sludge diluted 500 to 1 failed to kill perch in 14 days, and aerated bleach sludge diluted 400 to 1 did not kill perch in 5 days. Even if the dilutions are far greater than these figures, sulphite wastes may tend to drive away certain kinds of fish which, like trout and salmon, apparently seek pure waters. There can be no doubt that there are selective differences among fish as to oxygen requirements. It is said that certain of the grosser fish are capable of tolerating pulp-mill wastes, but acquire disagreeable tastes which make them nonedible.

Sulphite wastes may also injure the water of a stream in its use as a boiler water. In at least one instance, such wastes have been known to make the water of a large stream acid, and the damage done by them is often more subtle than that produced by the gross pollution in the vicinity of the mill. The salts of lignin-sulphonic acid, or whatever the compounds may be which result from the action of the acid bisulphite on the lignous and resinous compounds of the wood, have a most persistent odor; even when the sulphite wastes are greatly diluted, it can still be recognized. Formerly, the water supply of Augusta, Me.,† was taken from the Kennebec River, and the imperfectly filtered water often had a noticeable taste and odor resulting from the pulp-mill wastes at Winslow, 17 miles up stream. The water supply of Bangor, Me., is taken from the Penobscot River, and before filtration has the same characteristic taste. At times, the alkalinity is materially reduced and the coagulation of the water rendered difficult. At Watertown, N. Y., the Black River, polluted by sulphite wastes at Deferiet, Herrings, Carthage, and Lyons Falls, has the same taste and odor, which the filter has never been able wholly to remove. The odor is not removed by aeration and the use of chlorine seems at times to intensify it. The municipal authorities of Augusta wisely abandoned the Kennebec River supply and substituted a supply from a pond not far away. At Bangor, in spite of advice to seek another source, the Penobscot supply has been retained and improvements made in the filter plant.

* "The Pollution of Streams by Sulphite Pulp Wastes", *Water Supply and Irrigation Paper No. 226*, U. S. Geological Survey, 1909.

† "Quality of the Kennebec River Water", *Water Supply and Irrigation Paper No. 198*, U. S. Geological Survey, 1907.

Unfortunately, it is not the odor alone which causes trouble with down-stream water supplies. The sulpho-lignous organic matter interferes with the coagulation of the water, reducing the efficiency and increasing the cost of filtration. The exact nature of the reactions has not yet been accurately determined, but some studies have been made at the Watertown filter, which have led to modifications in the process and improvements in the results.

The water of the Black River is deeply stained, its average color being about 80 and its maximum color in different years running up to 135. The quantity of carbonaceous organic matter in the water is greater than that represented by the color. In a discussion* by the speaker before the Society in 1901, on decolorization of water, it was shown that in stained waters the organic matter, as indicated by the "oxygen consumed" test, was 0.125 part per million for each unit of color; but, at Watertown, tests have shown that the oxygen consumed corresponding to a unit of color is often double this quantity. The oxygen consumed is also higher at seasons of low stream flow, when the dilution is less than at other times. Some of the colorless organic matter found at Watertown may be due to sewage pollution, but inasmuch as sulphite waste shows a high figure for oxygen consumed, it is reasonable to suppose that these wastes are an important factor in the Black River. There are visible evidences of this pollution at the Watertown filter, as particles of woody fiber from the waste pulp can be easily detected by the eye; in fact, the superintendent of the filter is in the habit of making a daily record of the approximate quantity of pulp observed in the raw water. Phelps has shown that the "oxygen consumed" in sulphite waste liquor is from 36 000 to 60 000 parts per million; therefore, even after being diluted several thousand times, the water would contain as much organic matter, measured in terms of "oxygen consumed", as would correspond to a color of 100 units. It has been found, as a result of filtration experience, that the quantities of alum required for the coagulation of unstored colored waters free from sewage and industrial wastes, ordinarily bear a fairly definite relation to the color of the water; but in the case of the Black River water, the quantity of alum required is relatively great, largely because of the organic matter from the sulphite wastes. When the water filters were designed by Allen Hazen, M. Am. Soc. C. E., in 1903, it was decided, as a result of experiments made with colored waters, that a period of coagulation of 4 hours would be required, a time considerably longer than previous practice. Experience, however, has proved that even this was not long enough. In 1917, an existing settling basin was converted into a coagulation basin which increased the period of coagulation to about 8 days, and the results of this longer period have proved to be beneficial. Better results have been obtained, although the quantity of alum used has not been lessened. It will be seen, therefore, that, in various ways, sulphite waste pollution increases the cost of water purification.

This is not the whole story, however. Unless coagulation is well accomplished, that is, unless enough alum is used and the time of coagulation is sufficiently long, some of the alum in combination with the organic matter will pass through the filter. Three objectionable results follow, namely, the

* *Transactions*, Am. Soc. C. E., Vol. XLVI (1901), p. 141.

filtered water retains some of the "pulp-mill taste"; the water when heated for ordinary domestic service becomes corrosive, attacks iron, and causes red-water troubles; and the bacterial removal by filtration is not complete. These are all serious matters. Even with what is regarded as good coagulation, the sulphite taste may persist in filtered water.

At one time, as a result of experiments at Watertown, it was thought that basic alum was generally preferable to acid alum for water-filtration purposes. Later studies have made this doubtful. There are times, perhaps, when an acid alum may give better results than a basic alum, waters differ in this respect. With alum made at the filtration plant, as is now often the case, it may be possible to modify its character so as to obtain the best results for any particular water.

Engineers once thought that they had obtained a fairly complete understanding of this problem of coagulation, but experience with mechanical filters, although on the whole successful, has shown that there are many things to learn about coagulation, especially the coagulation of soft, colored waters and waters polluted with such wastes as those from pulp mills. The nature of the colloidal substances, the possible protective effect of colloids on bacteria, the relations between chlorine and organic matter, and the reaction between sulphate of alumina and organic colloids, are some of the subjects which chemists and biologists now have under consideration.

Enough has been said, perhaps, to show that the pollution of streams by pulp-mill wastes is a matter which may cause damage to down-stream riparian owners and affect the health and comfort of many people in communities which take their public water supply from polluted rivers. It also has a bearing on the general problem of conservation of natural resources. Pulp mills not only spoil the rivers, but they despoil the forests. Wood pulp is a useful substance, but there is hardly any raw material that is wasted so lavishly. Without doubt, chemical engineers can solve the pulp-mill pollution problem if capitalists will provide the means, the laws are ample to protect the down-stream riparian owners if they are enforced but, in the speaker's opinion, a better solution of the problem lies in preventive measures, that is, in measures which will protect the forests. Conservation demands that tree trunks suitable for lumber be used for that purpose. It is necessary to find methods of obtaining cellulose such that the newspaper which is in use a day and the paper towel which serves the purpose of a moment are not made at the expense of a tree which has taken twenty years to grow.

The speaker may be wrong, but it appears to him that there is now a greater indifference to stream pollution, a greater laxity in enforcing laws, than was the case before the World War. Probably, this is merely a part of the widespread lapse from law and order unfortunately so prevalent at this time. It is a condition which must not be allowed to continue. The pendulum may swing, perhaps, from too much laxity to too much rigidity. The present is a good time, therefore, to consider carefully in a broad spirit of co-operation and in a scientific manner, the best way of dealing with the whole subject of stream pollution. Certain things have been demonstrated by experience. The pollution of a stream may steadily increase without serious offense and with-

out attracting much attention, until suddenly a crisis is reached, the dissolved oxygen disappears from the water and the river is wrecked. It has been learned that it is cheaper and safer to protect a down-stream water supply by filtration than by up-stream treatment of sewage, but that a single line of defense is not enough. It has been learned that many kinds of manufacturing wastes impart tastes and odors to waters, which cannot be readily removed by water filtration and that chlorination sometimes accentuates them, and that these tastes and odors may be produced even when the polluting substances are very dilute. It has been learned that river-pollution problems are not all related to the public health. It has been learned that because rivers flow between States and from one State into another, the control of pollution by independent State action is not adequate to meet the situation, and yet the police power resides in the sovereign States. It is evident that some new mode of procedure is necessary to deal with the situation; yet it is doubtful whether any better legal remedies will ever be devised than the application of the principles of common law and the exercise of police power by the separate States. The speaker does not favor delegation of the police power to the Federal Government in this matter, and, at present, the powers of the Federal Government are limited to navigable streams.

A uniform policy throughout the country is much needed. To secure this, a thorough scientific, economic, and legal study of the whole subject of stream pollution should be made on a National scale by a joint committee representing the National bodies interested in the different phases of the subject, under the sponsorship of one of the Federal Departments with Congressional authority and an adequate appropriation. This committee, after several years of investigation, should formulate a policy, suggest model laws, and recommend their adoption by the several States. It may be possible to organize river districts independent of State boundaries, with commissioners whose duties would be to secure co-operative efforts to keep the rivers clean and to utilize the waters of the streams to the best advantage of all the people living within the districts, leaving all legal actions where they now are and where, in the interest of good government, they should remain. The whole subject at present is in a chaotic state. Some State Departments of Health attempt to exercise almost despotic powers over the streams; in other States, their action is chiefly advisory; and, in some States, there are pollution commissions independent of the health authorities. Although there has been a recent laxity in law enforcement, it is hoped that the next move will not be toward a too arbitrary enforcement of ill-considered laws, but that means will be found to accomplish by co-operative effort what is so difficult to accomplish by law. It would appear that the Society is one of the organizations which should take the lead in this important matter of conservation.

WASTES FROM PULP AND PAPER MILLS CHEMICALLY CONSIDERED

By H. W. Clark,* Esq.

There are two main points of view concerning pulp and paper-mill wastes: (1) That of the owner of the mill who wishes to discharge wastes of no value into the streams on which the mill is located; and (2) that of the sanitary engineer who wishes to keep the stream in as unpolluted a condition as can be reasonably required.

Where industrial streams are not used for water supply, about all that is necessary in the treatment of industrial wastes is purification sufficient to prevent the stream from becoming a nuisance to the community, on account of its appearance, deposits on its banks, and odors. If possible, it should be kept clean enough to be a source of enjoyment to this community. Where streams are polluted by pulp and paper-mill wastes too large in volume to be properly diluted and cared for by the volume of water into which they go, and this stream must be used farther down on its course as a water supply after filtration, efficient treatment of these wastes is not only desirable, but necessary.

The speaker began to investigate the pollution of streams by wastes from pulp and paper mills about twenty-seven years ago and has been obliged to consider the subject of paper-mill wastes both from the viewpoint of the sanitary engineer and the manufacturer who hesitates to expend large sums to satisfy extravagant demands for the prevention of stream pollution.

Many kinds of wastes result from the making of paper and a more or less complete classification of them is as follows: (1) The wastes from pulp mills where wood, either poplar or spruce, is treated; (2) the wastes from digesters in mills making paper from material other than wood pulp, that is, from old rope, carpets, bagging, old paper, etc., and as this stock is treated in digesters, the wastes resemble those from wood-pulp mills; (3) the waste liquor, very polluted, produced by washing and beating such stock before it is treated in digesters and made into paper; (4) the waste from mills in which rags only are the stock treated with milk of lime in rotary boilers; and (5) the wastes from making pulp of all kinds into paper.

At present, the wood-pulp mills treat either poplar, spruce, or hemlock, the poplar being treated by the soda process and the spruce and hemlock by the sulphite process. Owing to the decrease in the supply of poplar, the sulphite process is perhaps gaining materially over the soda process. Two classes of waste liquor are produced, one from each process. At many mills, the digester liquor from the soda process is evaporated and the used chemicals recovered, thus preventing the discharge of much waste liquor. The liquors from the sulphite process generally go to waste, that is, are discharged into the stream on which the mill is located. The following statements concerning two typical pulp mills in Massachusetts, one using the soda process and the other the sulphite process, can be made.

* Chf. Chemist, Massachusetts Dept. of Public Health, Boston, Mass.

In the pulp mill using the soda process, 2 500 lb. of soda ash are used for each charge in the digester, this soda being causticized 90% before use and the residual calcium carbonate resulting from this process used in sizing. Of the 2 500 lb. of soda used in each charge, about 500 lb. is new, whereas the remainder has been recovered from the black ash of previous digestions, the digester liquor having been evaporated and calcined. At this mill, about 5 000 000 gal. of this digester liquor is produced annually, of which only about 10% is wasted, being lost during the washing of pulp after digestion, the remainder being evaporated for this recovery of chemicals. The analysis of this waste liquor from the soda process is as follows:

	Parts per million.
Total solids (no suspended solids present)	132 000
Loss on ignition	72 100
Fixed solids	59 900
Alkalinity (methyl orange)	39 000
Free ammonia	34.00
Albuminoid ammonia	72.00
Oxygen consumed	27 600

Volume for volume, this liquor is perhaps one hundred times as deleterious to a stream as domestic sewage. It contains a large quantity of organic matter and its oxygen demand while comparatively slow, is enormous, perhaps twenty times that of average domestic sewage. In 24 hours, 1 gal. of this waste will absorb 10.78 grammes, or 7 544 cu. cm., of oxygen. It is so alkaline—practically 4%—that it destroys bacterial life in the water into which it flows, and it is deadly to fish. Fortunately, the volume wasted is small and will probably decrease as the recovery of chemicals increases in favor.

A different story must be told of the liquor from the sulphite process. At the plant under discussion none of the digester liquor is recovered, about 17 000 000 gal. being discharged annually into the stream on which the mill is located.

The speaker believes that in a few cases this liquor is concentrated by evaporation or is treated so that it becomes useful for certain purposes. It contains 4 000 parts per million of organic acid, which should make its recovery of value. During the World War, experiments were made looking to the recovery or manufacture of alcohol from it. An analysis of this waste from the sulphite process is as follows:

	Parts per million.
Total solids (no suspended solids present)	74 100
Loss on ignition	66 300
Fixed solids	7 800
Alkalinity (methyl orange)	—800
" (phenolphthalein)	—5 000
Sulphur dioxide (as sulphurous acid or sulphites)	400
Free ammonia	146
Albuminoid ammonia	62
Oxygen consumed	34 600

This waste is acid and contains practically as much organic matter as the soda-process waste. Its oxygen demand on the stream it enters, appears to be somewhat less, and it is slightly less deadly to bacteria and to fish. In 24 hours, 1 gal. of this waste will absorb 8.71 grammes, or 6 088 cu. cm., of oxygen. There is no reason why the treatment of this liquor should not be demanded where sanitary conditions require it, as it probably can be evaporated and products recovered which would pay at least for the cost of treatment. Neither of these liquors can be satisfactorily treated by any known method of purification other than evaporation and recovery of bodies of value. They are exceedingly inimical to bacterial life, and if mixed with sewage, or other liquors, and passed to filters, they destroy the value of such filters.

As stated previously, wastes from certain paper mills consist of the liquors from washing old stock worked up, from treating this stock in digesters, and from the paper machines. In such mills, soda ash, lime, bleaching powder, white clay, etc., are used and a large part of these chemicals are wasted. There is generally no saving of soda ash or other chemicals in mills using mixed stock. The true wastes, however, are largely carbonaceous, and in order to purify or clarify them satisfactorily, dependence must be had on straining, sedimentation with or without the use of precipitants, and filtration through filters of sand, cinders, or like material. In the treatment of domestic sewage, nitrification by bacterial action is depended on where a high degree of purification is required, but the small amount of nitrogen in paper-mill waste renders this process of little value.

Investigations at the Lawrence Experiment Station showed that when a liquor to be treated contained an x amount of nitrogen and from $10\,x$ to $12\,x$ of carbon, nitrification would still take place in a filter, but that it was practically killed when the amount of carbon was $13\,x$ or $14\,x$, or greater. In this investigation, studies of the behavior of paper-mill wastes under certain conditions of filtration were made, together with complete analyses of such wastes, to determine the relative amount of nitrogen and carbon present in them. Some bacterial action, however, does take place in filters receiving carbonaceous wastes, this purification without nitrification being due to certain bacteria which are active under conditions that prevent nitrification, but which cause chemical actions that break down organic matter and result in the setting free of carbon dioxide and nitrogen.

Much of the organic pollution in paper-mill wastes is in suspension, and a considerable part is quite readily removed by passing the liquors through fine wire screens. In some mills, a large part of the pulp formerly wasted from the paper machine is saved in this way, and a large part of the dirt in various wash waters can also be screened out. Besides screening, sedimentation is depended on at many mills to save pulp, and at such places aluminum sulphate is also generally used to aid sedimentation. The paper fiber saved in this way much more than repays the cost of construction and operation of sedimentation tanks and the aluminum sulphate used. The aluminum hydrate produced and unavoidably mixed with the pulp used, is of value, generally speaking, in the weighting of paper and often as much as 4 or 5 grains per gallon of sulphate is

used in this saving of fiber. The quantity of oxygen absorbed in 24 hours by wastes from a mill representing the class using mixed stock is shown by Table 2.

TABLE 2.

Sample.	Dissolved Oxygen Absorbed by 1 Gal. in 24 Hours.	
	Grammes.	Cubic centimeters.
Rotary boiler wastes	2.2720	1 589.0
Washer wastes	0.4920	344.2
Settled washer wastes	0.2272	158.9
Machine wastes	0.1136	79.5
Settled machine wastes	0.0304	21.2

When the speaker first began to study paper mills and their wastes, hardly a "save-all" was in use and none of the elaborate sedimentation and precipitation tanks that are in common use to-day. Besides the saving of machine wastes by the tanks, etc., the pollution of streams is prevented by screens and sedimentation tanks through which are passed the waste liquors from the washing of old stock. About 30% of the matters in suspension is generally eliminated in this way by 4 hours of sedimentation and from 90% to practically all the matter in suspension can be removed if 75 to 100 grains of aluminum sulphate per gallon, are used. This means from 10 000 to 14 000 lb. per 1 000 000 gal. and is a large amount of precipitant, but it is being used in some mills where it is necessary to prevent the pollution of streams. Where several million gallons of waste are produced by one mill, the removal by sedimentation alone of even 30% of the matter in suspension means much reduction of river pollution. More than this, sedimentation and filtration can be depended on to treat the mixed wastes for further purification. The rates of filter operation vary with the quality of the liquor being treated, but rates of from 200 000 to 500 000 gal. per acre per day are used with good results. By a combination of all these methods—screening, sedimentation, and filtration—it is often possible to remove 70% or more of the primary polluting matters of paper-mill wastes. Apparently, however, the only wastes recovered with profit as yet are those from the soda-pulp process and the wastes from the paper machine. Much research work is being done, and it is probable that valuable discoveries will be made.

THE TREATMENT AND DISPOSAL OF STRAWBOARD WASTES

By H. B. Hommon,* Esq.

This paper gives a complete account of the studies made at the American Strawboard Mill, Noblesville, Ind., for developing methods to treat wastes resulting from the manufacture of paper from straw.†

Process of Making Paper from Straw.—Strawboard mills are generally located in wheat-growing districts. The straw is purchased from the farmers, baled, and shipped to the mills where it is stacked in large piles. The first step in the process of making paper is to cook the straw in large ellipsoidal rotating steel boilers with steam and lime, about 1 ton of the mixture to 6 tons of straw, until the woody fiber is softened, and the whole mass has been reduced to a dark yellow pulpy consistency. The yield of pulp at this point is about 75 to 80% of the weight of the original stock. The pulp is removed from the boilers, allowed to drain, and then placed in beaters and washers, where it is broken up and the lime, fine particles of straw, and other foreign material washed out.

From the washing machines, the pulp is carried by water to the paper machines, where it is taken up on felts and delivered to a train of hot rolls that turn out the finished product.

Volume of Wastes Produced.—Of the many sources of wastes from a strawboard mill, only two produce large quantities, namely, the washing and the paper machines. These two wastes come from separate parts of the mill and differ widely in composition, but they are approximately the same in quantity. While the tests were being conducted at Noblesville, a survey was made of seven other strawboard mills, in order to determine how far the analyses and flow data obtained at the experiment station were representative of the entire strawboard industry.

As already stated, the pulp from the cookers or rotaries is washed to remove the lime, fine particles of strawboard, and other foreign material. The quantity of water used for washing the pulp varied considerably at the different mills where measurements were made, but the average was 18 200 gal. per ton of strawboard made. This figure checks closely the average for a long period at the mill where the experiments were conducted.

The waste from the paper machines consists of the water used to carry the pulp to the train of rolls. The measurements obtained at the various mills visited, showed variations, but the average, 19 900 gal. per ton of finished product, was almost identical with that obtained from the flow data at the experiment station. Therefore, about 38 500 gal. of waste was produced for each ton of strawboard made.

Composition of Wastes.—The waste from the beaters or washing machines was by far the more concentrated of the two, as it contained the chaff, minute particles of straw, and small particles of other organic matter washed from

* San. Engr., U. S. Public Health Service, San Francisco, Calif.

† Data taken from *Bulletin No. 97*, U. S. Public Health Service.

the pulp after digestion in the boilers. This waste also contained the lime washed from the digested pulp.

When the survey was made of the seven strawboard mills to determine the volume of wastes produced, a series of composite samples were collected from the wastes from the washing and paper machines and shipped to the central laboratory in Cincinnati, Ohio, for analysis. The results of the analyses of the washing machine wastes showed that the total suspended matter varied from 3 000 to almost 9 000 parts per million; the suspended matter in the supernatant liquor, after 24 hours of settling, varied from 450 to 2 400 parts per million; the organic nitrogen, from 47 to 105 parts per million; the alkalinity as carbonates, computed as $CaCo_3$, amounted to 1 870 parts per million; the oxygen consumed varied from 1 480 to 3 400 parts per million; and the oxygen demand, 10 days at 20° cent., from 1 850 to 3 600 parts per million.

The waste from the paper machines contained only the small quantity of fiber and other finely divided material that passed through the screens, together with the lime left from the washing process. The analyses from the mill where the tests were made and from the other seven mills covered in the survey, varied within the following limits: Total suspended matter, range 440 to 991 parts per million; suspended matter in supernatant liquor after 24 hours of settling, 60 to 460 parts per million; total organic nitrogen, 10 to 43 parts per million; carbonate alkalinity found in only three wastes of the eight reported; oxygen consumed, 191 to 970 parts per million; and oxygen demand, 10 days at 20° cent., 111 to 890 parts per million.

The analyses of the composites of the two wastes at the experiment station for the period of the tests checked the averages of the results from the mixed wastes at the other seven mills, within reasonable limits.

On the basis of the figures given for the average total volume of waste per ton of strawboard manufactured, and on the rated capacity of the mills in the United States in 1918*, there were approximately 20 000 000 000 gal. of waste discharged from the various plants during the year. Computed on the basis of the average suspended matter in the mixed wastes from all the plants visited, there were approximately 161 000 tons of dry suspended solids discharged from the strawboard mills in 1918. Much of the material was short fibers of straw, which the type of machinery in use at that time could not save.

Treatment of Wastes.—The experiment station was operated at the American Strawboard Mill from January 1, 1915 to June 30, 1916. The test units consisted of two settling tanks each 8 ft. in diameter by 10 ft. deep; one chemical reaction tank, 6 ft. in diameter and 10 ft. deep; one chemical settling tank, 8 ft. in diameter and 10 ft. deep; one chemical solution tank, 5 ft. in diameter and 6 ft. deep; one mechanical filter, 8 ft. in diameter and 6 ft. deep; two filters, 8 ft. in diameter and 10 ft. deep; one filter, 6 ft. in diameter and 10 ft. deep; and one filter, 8 ft. in diameter and 6 ft. deep.

From January 1 to July 1, 1915, the plant was operated on the principle of mechanical filtration. Alum alone and lime and iron were used as coagulants. The results obtained were unsatisfactory, due mainly to the large

* Lockwood's "Directory of the Paper and Stationery Trades", 1918.

quantities of chemicals required for efficient coagulation, the very low rates of filtration through the mechanical filter, and the high percentage of water required to wash the filter. As this method of treating the waste was impractical, further description of the plant, or discussion of the analyses of the various effluents, will be omitted for this period of operation.

During July, 1915, the plant was remodeled and operated until the close of the tests on the principle of biological treatment of the wastes. The two settling tanks were retained and operated as during the first period, but all the other tanks were turned into filters. The filters were constructed as follows: One, 6 ft. in diameter, having 5 ft. of limestone screenings; one, 8 ft. in diameter, having 5½ ft. of 1½-in. limestone; one, 8 ft. in diameter, with 5 ft. of unscreened cinders; one, 8 ft. in diameter, with 5 ft. of screened cinders; and one small screened cinder filter, 4½ ft. deep.

Results Obtained at the Experiment Station During Period 2.—The test units were operated for about one year in this period, and the results showed that strawboard wastes of the character produced at the American Strawboard Mill in making paper from straw could be treated so that the final effluent could be discharged into a stream of water having a dilution factor of at least 5 or 6, without creating a nuisance in the stream, or killing fish.

The weighted average for the suspended matter in the mixed raw waste for Periods 1 and 2 was 1 760 parts per million. During Period 2, the averages for total nitrogen and oxygen consumed were 29 and 910 parts per million, respectively. The carbonates and bi-carbonates were 141 and 598 parts per million, respectively. The oxygen demand at room temperature for 24 hours was 40 parts per million.

The raw waste was settled in tanks for about 2 hours, and the average suspended matter in the effluent was 680 parts per million, which is a reduction of 53 per cent. This was computed on the suspended matter in the raw waste during Period 2. The advantage of longer storage periods than 2 hours was practically negligible. The total nitrogen averaged about the same for the tank effluent as for the raw waste. The carbonate alkalinity was reduced by the tanks from 119 parts per million in raw waste to 63, and the bi-carbonate was increased from 533 to 558 parts per million. The average for the oxygen consumed was reduced from 720 to 575 parts per million.

The effluent from the tanks was treated on filters of the different sizes, kinds, and depths of filtering material already described. Filters of coarse and fine limestone and of unscreened cinders did not give satisfactory results and discussions of them will be omitted. Two filters of screened cinders, one 8 ft. in diameter and 5 ft. deep, and the other, 4.5 sq. ft. in area and 4.5 ft. deep, produced satisfactory effluents. The smaller of the two filters was in operation 11 months and the larger, 9 months.

The average analyses of the effluent of the large, screened, cinder filter compared with the average results from the influent are given in the Table 3.

The suspended matter in the effluent of the large, screened, cinder filter had none of the characteristics of that in the effluent of the settling tanks or in the raw waste. It was more like humus. The final effluent had a slight

yellow cast and there was no odor. The nitrification was low, but samples diluted 1:3 with tap-water were stable by the methylene blue test for 90 hours.

TABLE 3.

	Influent, in parts per million.	Effluent, in parts per million.
Suspended matter	918	115
Carbonates as $CaCO_3$	121	29
Bi-carbonates as $CaCO_3$	528	417
Oxygen consumed	742	133
Oxygen demand (24 hours, room temperature)	54	9.5
Nitrogen, total organic	29	9.1
Nitrogen as nitrites	....	0.035
Nitrogen as nitrates	....	1.3
Hours to reduce methylene blue at room temperature, dilutions, 1:10 and 1:3, respectively	40	90

In considering the results of the analyses of this filter effluent, it should be borne in mind that the organic matter of the waste was mostly cellulose that had been worked over in the bed, and that in its final condition it was not different from the material washed from woods or lands covered with decayed vegetation. When the filter was examined at the close of the tests, the top layer of material had a deposit resembling the original pulp; but below the upper half of the bed, the color of the deposit was dark and it was alive with earth worms and other small organisms. The odor was much the same as that noted when digging into soil rich with decayed organic matter.

The filter contained considerable organic matter, but it did not have the same effect on the effluent that an equal amount would have on a sewage filter, probably for the reason that the clogging material was of uniform composition and the life in the filter was capable of reducing it before anærobic action could be established. After the filter was examined, it was flushed with water and the filtering material thrown out of the beds. The first water from the flushing carried out large quantities of black flocculent matter and masses of earth worms and other organisms, and, later, the accumulation from the top layers came through. While digging out the cinders, it was observed that the voids were fairly clear and that the material remaining after flushing was gathered around the filter media. It is believed that cinders screened over a ½-in. screen, or thoroughly washed with water, can be used for many years to treat settled strawboard wastes, but it may be necessary to flush the beds about once a year to remove the clogging material from the lower half of the bed. There probably would be no objections to using settled waste for flushing, but if water is available it should be used, as it would freshen the filter and not add the same burden of organic matter to the receiving body of water that would result from using the settled waste.

Settling Period and Rates on Filters.—The settling periods in the tanks at the experiment station varied from 2 to 8 hours. The suspended-matter results for the various periods showed conclusively that 2 hours of settling was sufficient to remove practically all the settleable matter that could be removed by tank treatment in an economical period of time. The screened

cinder filters were operated for several months at a net rate of 400 000 gal. per acre per day, and the results obtained were satisfactory. This rate has been set as the maximum for settled strawboard wastes, and it is believed that it can be maintained for many years, provided the filters are flushed with water or tank effluent whenever they become clogged so that the influent does not flow readily through the beds.

Treatment of the Wastes by the Activated Sludge Process.—Laboratory tests were made to determine whether this process would be applicable to this class of wastes. Air was blown through sewage in large-bore, glass tubing until a satisfactory floc had been obtained and then waste was added gradually to replace the sewage. The results obtained after prolonged aeration were not satisfactory as the supernatant liquor after settling 30 min. invariably contained about 105 parts per million of suspended matter and the color was only slightly less than that of the raw waste. The analyses did not show as high degree of purification as that obtained by the tanks and filters.

Accumulation, Composition, and Disposal of Sludge.—Careful measurements and analyses were made of the sludge deposited in the tanks. The measurements showed that about 2.75 tons of dry solids were deposited per 1 000 000 gal. of waste treated and this, computed to 87% wet sludge, gives 24 cu. yd., or 0.9 cu. yd. per ton of product.

The analyses of the sludge in different stages of decomposition, and of horse manure, are given in Table 4.

TABLE 4.—Analyses of Strawboard Waste Sludge and Horse Manure.

Source.	Percentage (Dry Basis 100° Cent.)			
	Total nitrogen.	Calcium as $CaCO_3$.	Total phosphorus as P_2O_5.	Total potassium as K_2O.
Fresh sludge from settling tank.....	0.69	21	0.38	0.54
Digested sludge from settling tank....	1.0	23	0.48	0.42
Sludge from old settling pond.....	0.66	37	0.29	0.25
Horse manure* (including litter.).....	1.7	....	0.26	1.50

* Data from *Bulletin No. 246*, Ohio Agricultural Station, p. 726.

The disposal of the sludge presents a rather difficult and expensive problem. On the basis of the data obtained in the tests, there would be produced at the American Strawboard Mill about 3 tons of dry solids per 24 hours, or about 26 cu. yd. of wet sludge. The only practical method developed for disposing of the sludge was to dry it on shallow beds of cinders and apply it to land under cultivation for grain grown in sections where wheat is raised. Field tests were made, using the dried sludge as a fertilizer, and satisfactory increases in yield were found for corn when 8 tons per acre were used. As nearly as could be determined, the sludge had about the same value as a fertilizer as ordinary yard manure. In small box tests, the dried sludge invariably increased the yield of wheat, oats, and vegetables.

Effect of Filtered Waste on Fish Life.—A small box, 3½ ft. long by 2½ ft. wide by 1 ft. deep, was placed under the outlet from the large, screened filter bed. The effluent discharged into this box was diluted with 1 part of fresh water, and into this mixture 20 minnows were placed. In this dilution, the fish lived from May 8th to July 1st, when the experiment station was dismantled.

Treatment Plant Recommended.—On the basis of the data obtained in the tests, it was recommended in the report that settling and sludge storage capacity of about 975 cu. ft. per ton of daily output from the strawboard mill be provided in ordinary plain settling tanks. For drying the sludge, it was recommended that 875 sq. ft. of filter area be provided for every ton of strawboard made and that the beds be made of unscreened cinders about 10 in. deep.

The filters used in the tests that were most satisfactory, were made of screened cinders 5 ft. deep, and the highest rate of treatment that gave satisfactory results was 400 000 gal. per acre per day. On the basis of these data, it was recommended that 4 171 sq. ft. of filter area be provided for each ton of product made, or 772 cu. yd. of cinders per ton.

Conclusion.—At the time the experiment station was placed in operation, no practical method was known for treating wastes produced from the manufacture of paper from straw. Where this type of waste had caused serious nuisance in the receiving bodies of water, dikes had been constructed, sometimes enclosing as many as 50 acres of land, and the ponds thus made were used as a means of storing wastes. Evaporation and seepage into the ground were taking care of the waste.

The testing station was planned and operated to modify the character of the waste so that the organic matter in the final effluent, whether in suspension or solution, would not draw heavily on the oxygen supply of the receiving body of water or kill fish, and would not form offensive sludge deposits.

It was believed that this was as far as the first studies should go, leaving the subject open for further investigation, with particular reference to the effect of the treated waste on water filtration plants purifying water from bodies of water containing the waste. This phase of the problem can be studied only after large treatment plants have been placed in operation.

The results obtained in the tests showed that strawboard waste can be treated at a reasonable cost, so that a body of water affording a dilution factor of at least 5 or 6 can receive the final effluent without danger of causing a nuisance or killing fish. In low dilutions, there will be some increase in color from the treated waste and an increase in the alkalinity, but no harmful bacteria will be added, and it is believed that domestic sewage from sprinkling filters will have more effect on a stream of water than an equal volume of the treated waste.

A complete description of the experiment station, together with a large amount of analytical data and the final recommendations in detail are given in the report of the tests.

RELATION OF WATER POWER TO THE PULP AND PAPER INDUSTRY IN CANADA

By J. B. Challies,* M. Am. Soc. C. E., and I. J. Johnston,† Esq.

The purpose of this paper is to illustrate the important assistance contributed by various branches of engineering to the development of pulp and paper manufacture in solving the unusually large power requirements of this industry. Motive power for the production of pulp and paper is vital, being almost as important as the raw material. The importance of cheap power may be judged from the fact that it requires practically 100 h. p. to make 1 ton of paper per day. In the various processes followed, the average figures of a large Canadian mill show that mechanical pulp requires 73 h. p. per ton of daily output, of which 67 h. p. is for grinding alone; sulphite pulp requires 8.7 h. p. per ton of daily output, and in other large mills as high as from 20 to 30 h. p., whereas the production of newsprint from pulp consumes 12 h. p. for the same unit output. The continuous operation of mills in this industry, usually 24 hours per day, permits an advantageous use of power, and direct water power or hydro-electric energy further allows a cheap unit cost for the amount consumed.

Importance of Pulp and Paper Industry in Canada.—The development of this industry in Canada has been rapid and the cheap power required brings it in close touch with the hydraulic resources. These facts recently led to a special survey of conditions by the Dominion Water Power Branch of the Department of the Interior, Ottawa, and the various data here presented are based largely on the information thus gathered. The remarkable expansion during the last generation may be judged from pulp and paper export trade of Canada, which is said to have amounted to only $120 in 1890 as compared with more than $100 000 000 in 1922. According to the figures of the Bureau of Statistics, for 1920, the pulp and paper industry in Canada represented a total capital investment of $347 553 333, found employment for 31 298 persons whose yearly wages and salaries amounted to $45 253 893, and the value of the products totaled $214 421 546. The fact that this industry requires large quantities of cheap power practically restricts it to hydraulic energy and the position acquired by Canada in this field rests on adequate and abundant water powers well distributed among extensive forest resources. The importance of cheap power in the manufacture of pulp and paper may further be gauged by a comparison with other Canadian industries, the power requirements of which are also large. Census figures for 1920 show that for every 100 h. p. installed in the pulp and paper industry, lumbering had only 60 h. p.; flour mills, 20 h. p.; and cotton mills, 10 h. p.

Total Power Installation.—In this paper and in Tables 5 and 6, the general term "pulp and paper mills" refers to all mills, whether they produce only pulp or paper or both these products.

Fig. 1 is a map of Canada showing the location of pulp and paper mills operated by water power or hydro-electric energy.

* Director, Dominion Water Power Branch, Dept. of the Interior, Ottawa, Ont., Canada.
† Ottawa, Ont., Canada.

The energy derived directly or indirectly from water power for the operation of pulp and paper mills in Canada amounts to 637 080 h. p., of which 476 503 h. p. is controlled directly by the pulp and paper organizations and the additional 160 577 h. p. represents purchased hydro-electric energy. This paper deals with only the important relation of water power to the pulp and paper industry and does not include data on mills in which steam is used as motive power. In Canada, the use of steam power in this industry is very limited, being prompted in most cases by special conditions, such as operations in which refuse from the manufacture of lumber can be used as fuel. The census returns of 1920 show a total steam-power installation in pulp and paper mills of only 62 400 h. p., and if the capacity of the three or four larger steam-operated mills in which special conditions obtain, is excluded, the remaining unit capacity is small.

Electric Drive in the Industry.—The electric drive is an important consideration. Of the entire water-power installation for the various mills, a total of 178 911 h. p. is converted into electrical energy before it is used to operate the pulp and paper machinery. The advantages of the electric drive are many; a uniform speed is assured, which is of primary importance in governing the quality of the product; it also allows the centralized operation of a large mill receiving power from several hydro-electric sources, and a closer study of power conditions, adjustment, and consumption is permitted. In a number of cases, the hydro-electric power is generated quite a distance from the mill in which it is used. In most instances, the mill is located at a water-power site and when gradual expansion has necessitated additional power, another near-by hydraulic site has been developed and hydro-electric energy is transmitted to the mill to permit centralized operation.

its allied organizations supply about 80 000 h. p., and in Ontario, the Hydro-Electric Power Commission and Toronto Power Company together supply about 55 000 h. p.

Motive Power by Provinces.—The method of producing power for the operation of pulp and paper mills is summarized by Provinces in Table 5. Although a large amount of water power is still used to drive the mill equipment directly from turbines, a considerable part is utilized by first converting it to electric energy for the more convenient electric-motor drive.

Characteristics of Geographic Groups.—Table 6 illustrates the predominating features in certain districts into which Canadian mills may be arbitrarily grouped. Perhaps the greatest contrast exhibited in this table is between the class of mills found in the Niagara and Toronto, Eastern Ontario, Montreal, and Quebec groups, where a large number, the average capacity of which is small, produce much of the miscellaneous kinds of paper, whereas the British Columbia and more northerly groups in Ontario and Quebec comprise mills of large capacity, requiring much power to produce principally pulp and newsprint.

General Conditions in Each Province.—The Province of Quebec is slightly ahead of Ontario in the pulp and paper industry. British Columbia ranks next, followed by New Brunswick and Nova Scotia. This industry has yet to be introduced in the prairie Provinces.

The Province of Quebec has 54 mills with a total of 312 867 h. p. The three largest mills are at Grand Mère, Kenogami, and Shawinigan, each of which requires about 25 000 h. p. Among other large mills requiring between

10 000 and 25 000 h. p., are those at Hull, East Angus, Brompton, Chicoutimi, Clark City, and Cap Magdelaine.

The Province of Ontario has 41 mills with a total of 242 746 h. p., including that at Iroquois Falls, reputed to be the largest, which requires 52 000 h. p. Another mill is located at Ottawa with 28 789 h. p., and mills requiring between 10 000 and 20 000 h. p. are located at Sault Ste. Marie, Espanola, Sturgeon Falls, Thorold, Fort Frances, and Fort William.

British Columbia has 5 mills with a total of 48 800 h. p., the two largest being at Powell River and Ocean Falls with respective installations of 24 000 and 20 550 h. p.

New Brunswick has 3 mills with a total installation of 14 668 h. p., and Nova Scotia has 10 mills with 17 999 h. p.

Future Power Requirements of the Industry.—It has recently been estimated that the present demand for pulp wood requires about 20 000 acres of Canadian forests per year and, following the trend of other commodities, this consumption will probably increase rapidly. Although the reforestation now being extensively conducted, will help later to remedy this depletion, it must be noted that from 50 to 100 years are required for suitable growth. Until full results are realized, it will doubtless be necessary to extend wood pulp operations farther and farther north and the bountiful supply of Canadian water power in these regions will facilitate the fullest development of this industry.

MARINE BORERS

By W. G. Atwood,* M. Am. Soc. C. E.

Regardless of the enormous damage done by marine borers for centuries, they have been given very little systematic study. The *Transactions* of the Society contain four papers on the subject.†

The paper by Mr. Snow is a scientific study of the various borers themselves, whereas the other papers treat largely of methods of protection from their action. In various papers on harbor construction, many references to the subject are also made.

As far as is known, the studies now being carried on in the United States by the National Research Council, and in Great Britain by the Institution of Civil Engineers, are the first attempts to solve the economic problems involved in harbor construction in salt water by the close co-operation of biologists, chemists, and engineers. Both organizations are studying the borers as well as materials, methods of construction, and methods for the protection of existing structures threatened with attack by them.

Marine borers are found in fossil form and have been the source of great economic loss ever since the first structures were built in or floated on salt water. They are mentioned in the Bible where, according to a German biologist, F. Moll, the following passage occurs: "As the worm the wood so an ugly wife destroyeth her husband," and the writings of many of the early Greek and Roman scientists contain references to them. In early times, the true classification of the borers was not recognized, and those of the teredo type were thought to be worms.

The destructive borers so far as identified, belong to two families, the *Mollusca* and the *Crustacea,* shown on Fig. 2. The teredo group belongs to the family of mollusks, as do the oyster and clam, whereas the crustacean group, allied to the lobster and crab, are represented by the limnoria, sphæroma, and other similar organisms. The mollusks are also represented by the pholas, martesia, and other forms in which the body of the animal is inside the shell like that of the oyster, instead of outside of it, like the teredo.

Of the two families of borers, the mollusks are probably the more dangerous, because they enter the structure through minute holes and do their excavating out of sight, whereas the crustaceans bore comparatively shallow holes of small diameter, honeycombing the surface. The work of the latter group, therefore, can readily be discovered by inspection.

The beginning of modern literature and study of these organisms dates back to the Sixteenth Century. This study was first brought about by the destruction of the dikes of Holland, just as the beginning of the study now going on in the United States can be traced to the rapid destruction between

* Director, Committee on Marine Piling Investigations, National Research Council, New York City.

† "*Teredo Navalis,* or Ship-Worm", by the late G. W. R. Bayley, M. Am. Soc. C. E., *Transactions,* Am. Soc. C. E., Vol. III (1875), p. 155; "The Preservation of Timber", by the late J. W. Putnam, Assoc. Am. Soc. C. E., Vol. IX (1880), p. 206; "Protecting Piles Against the *Teredo Navalis* on the Louisville and Nashville Railroad Company's Lines", by Richard Montfort, M. Am. Soc. C. E., Vol. XXXI (1894), p. 221; and "Marine Wood-Borers", by Charles H. Snow, M. Am. Soc. C. E., Vol. XL (1898), p. 178.

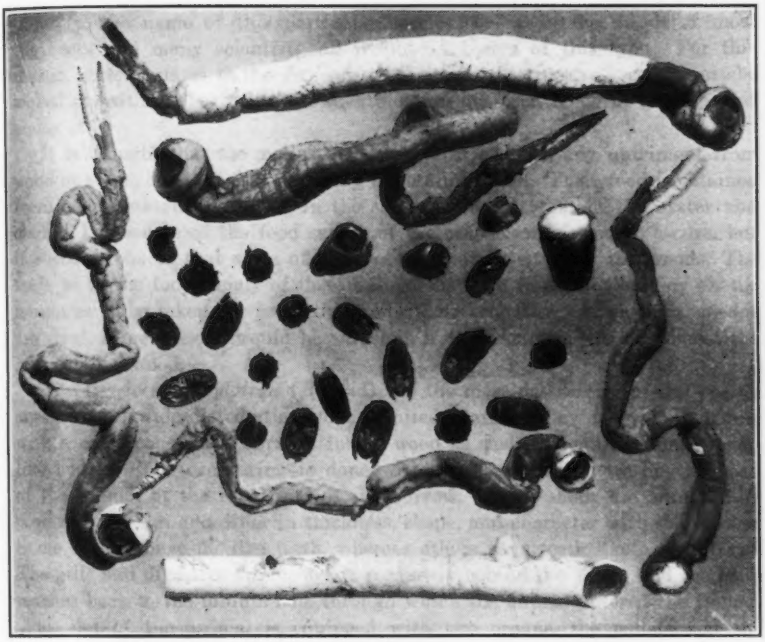

FIG. 2.—MOLLUSCAN AND CRUSTACEAN BORERS.

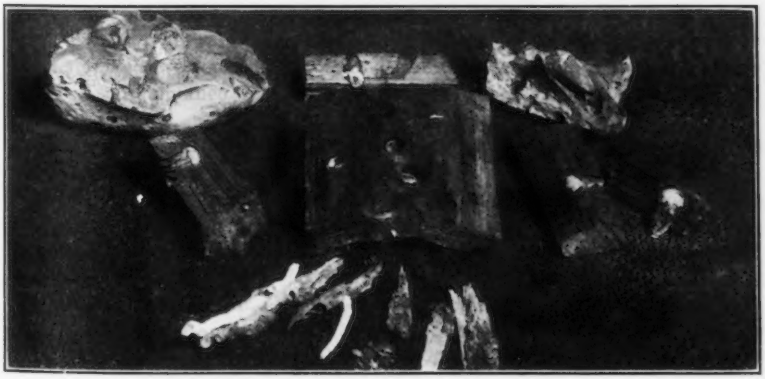

FIG. 3.—SOME ROCK AND WOOD-BORING MOLLUSKS.

1918 and 1921 of the structures in the upper part of San Francisco Bay. The destruction in Holland was caused by the species, *Teredo Navalis*, and, unfortunately, the name of this particular species covers, in the minds of most engineers and many scientists, all molluscan borers of this type. For this reason, statements as to the presence of this most destructive species must be looked on with doubt, unless the identification has been made by a competent biologist.

It is thought that the molluscan borers do not obtain any nutriment from wood or stone, but that they bore only to obtain shelter. Their food is obtained from the plankton of the sea in the same manner as that of the oyster and clam. The source of the food supply of the crustaceans is more obscure, but it seems probable that some of them obtain nutriment from the wood. The facts as to the food supply of these animals have an important bearing on the measures to be taken for protection from their activities. If chemical means are used, some poisons would be valueless if the organism did not digest the impregnated wood.

The teredo and *Xylotrya* (*Bankia*) are the most destructive of the boring organisms of wide distribution in the United States. They excavate and line, with a calcareous shell, burrows in the wood as shelters for their long worm-like bodies. The excavating is done with the shells which are on the head of the animal at the inner end of the burrow. These shells are actuated by powerful muscles and differ in thickness, shape, and character with the species. Some species have file-like teeth, whereas others have teeth like a wood rasp. The gills and digestive organs are immediately behind the shells, and the body reaches back to the minute hole through which the animal entered the timber. This end of the animal is equipped with two organs, the pallets and the syphons. The structure and shape of the pallets differ in the different species, and the characteristics of these organs form the most important means of identification. The pallets of all species have some common characteristics of form and all serve the same purpose. Each pallet is concave on the inner and convex on the outer surface, and when brought together they form a cone with the point outward. Ordinarily, the pallets project from the wood into the water and are separated. When disturbed, the animal brings the pallets together and pulls them in, thus closing the hole and shutting out enemies and harmful material.

The syphons are two muscular tubes normally extended between the pallets outside the timber. When in this position, a constant stream of water carrying food passes in through the incurrent syphon and a corresponding stream carrying the body wastes and the saw-dust resulting from the boring, passes out through the excurrent syphon. The syphons of the *Teredo Navalis* extend from 1 in. to 1½ in. outside the timber, and a badly infested pile looks as if it was covered with grey moss. When the animal is disturbed, its syphons are retracted inside of and protected by the pallets when they are closed, and no sign of the presence of the animal is shown outside the timber.

The rate of boring and of growth of the body of the animal is the same, so that the burrow is always filled. This rate varies normally from 1 in. to 2½ in. per month for the more common species. In the float of the New Jersey

Oyster Commission that was destroyed in Barnegat Bay in 1921 by the *Teredo Navalis,* there were 80 teredo per cubic inch. They were so crowded that they could not grow, but at 6 weeks of age they were about ¾ in. in length and sexually mature.

The food of these animals consists principally of the countless marine organisms known to zoologists as "plankton." Dr. C. A. Kofoid, Professor of Zoology of the University of California, states:

"The ocean in common with lakes and rivers produces each year a crop or rather a succession of crops of microscopic food known as plankton on the ocean meadows whose tonnage per acre and whose chemical composition compares with the forage crops of wild and cultivated lands."

The molluscan borers feed on this exclusively, appropriating it as it passes their doors. They never go foraging, except in the case of the free-swimming larvæ. The variation in the supply of this food is seasonable and is largely responsible for the variation in the activity of the borers. Although in infested territory there is generally sufficient food supply for the maintenance of life, there is not always enough to enable the borers to maintain maximum activity. The period of reproduction generally corresponds to that of ample food supply.

The life history of the *Teredo Navalis* and *Xylotrya* (*Bankia*) is fairly well known. The young of the *Teredo Navalis* are born as free-swimming larvæ, whereas the eggs of the *Xylotrya* are ejected by the female, fertilized, and the larvæ hatched in the water. From this time, the history of the larvæ of both species is the same. The Dutch naturalist, Sellius, states that in the body of a medium sized *Teredo Navalis,* he found 1 874 000 larvæ. The *Xylotrya* (*Bankia*) does not produce so many eggs and as its method of reproduction results in a much lower rate of survival, the *Xylotrya* (*Bankia*) is not as destructive as the *Teredo Navalis.* The larvæ of both species are free-swimming for about a month, or until the weight of the shell is sufficient to sink them. When they come in contact with a satisfactory piece of timber, they attach themselves to it by a sticky thread and commence boring.

The rapidity with which these types of borers spread, can be readily appreciated when it is realized that a single, thoroughly infested pile may contain from 50 000 to 100 000 females, each producing more than 1 000 000 larvæ per year. The depth in which these borers work is not known exactly, but it probably varies with the species. Both species under consideration will work to a depth in excess of 10 fathoms, and some species were dredged from great depths by the *Challenger* Expedition.

The martesia is another type of molluscan borer which is present, as far as known, only in the Gulf of Mexico. It greatly resembles the clam in appearance, the body of the animal being inside the shell, and is seldom more than 1 in. in length. This organism is very destructive, but as far as known, its range is limited. It differs from most of the other borers in the fact that thorough creosoting gives no protection. Very little is known of its life history.

The pholas, known on the Pacific Coast as the "rock-boring clam", somewhat resembles the martesia, except that it reaches a greater size. It bores

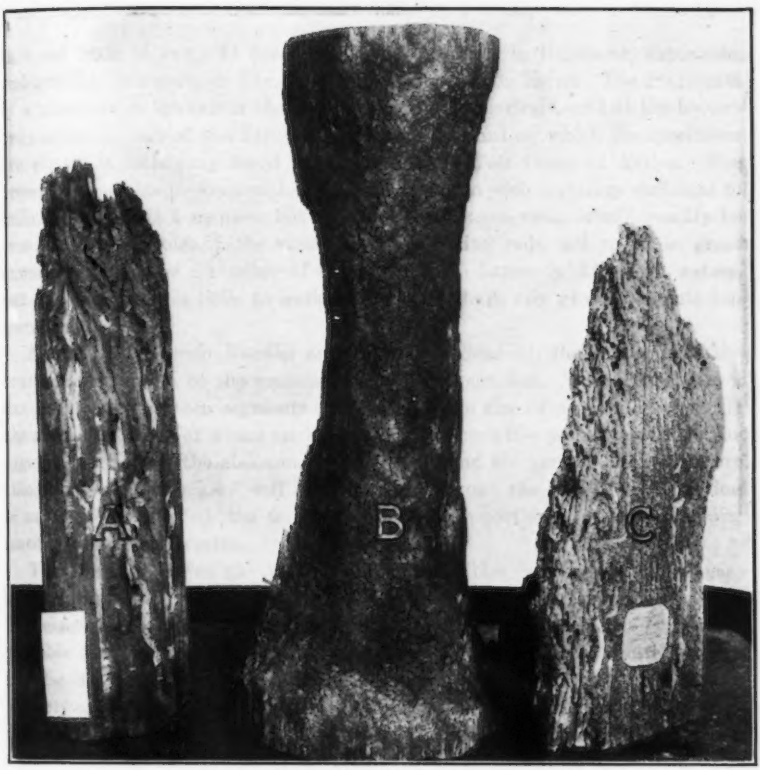

FIG. 4.—RESULTS OF LIMNORIA AND TEREDO ACTION ON PILING.

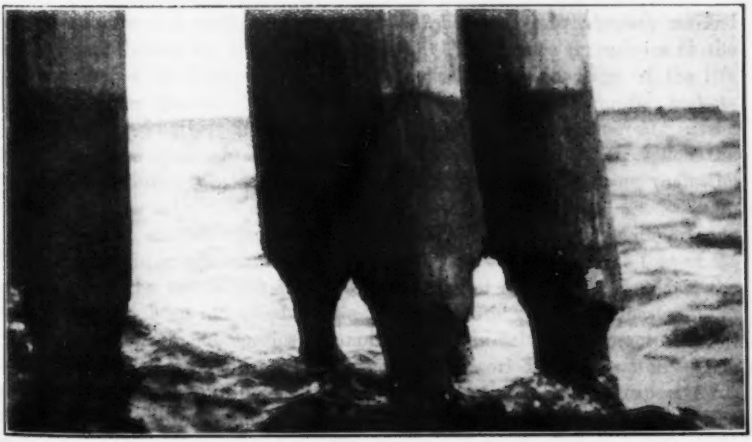

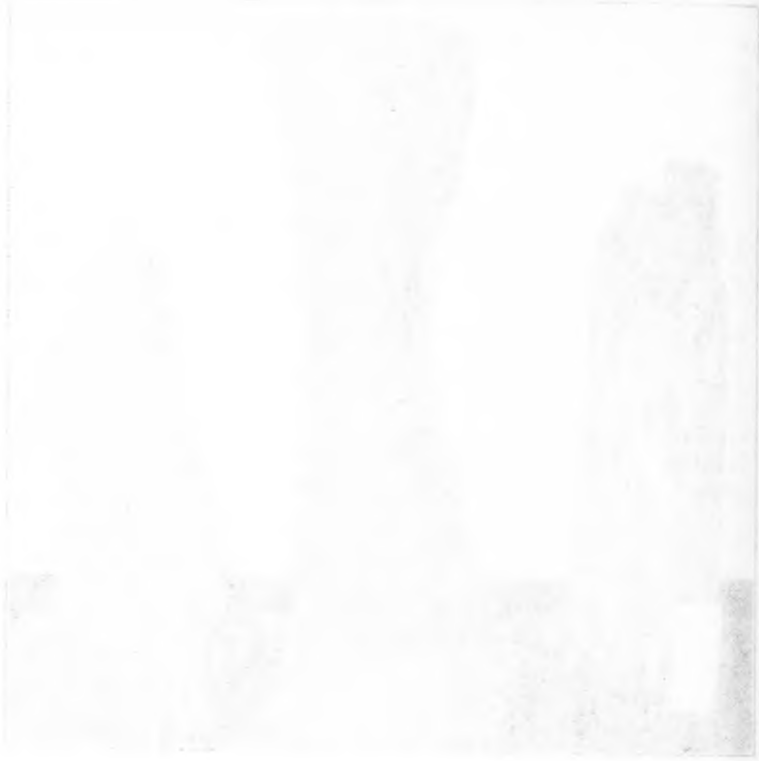

FIG. 5.—LIMNORIA ATTACK ON PILES ON ATLANTIC SEABOARD.

in wood little if any. It does bore, however, freely in limestone, sandstone, and granite, as shown on Fig. 3, at the right and left, above. The fragments of a pine pile in the center show the attack of the martesia, and at the bottom are burrow linings of the *Teredo Navalis*. The board on which the specimens are placed is mahogany bored by teredo on the West Coast of Africa. The presence of pholas in concrete has not been reported with certainty sufficient to indicate that it is a menace, but if it does attack concrete, it will readily be seen that a few holes in the vicinity of reinforcing rods will result in great damage. There are a number of other molluscan borers in American waters, but thus far there is little to indicate that they have any great economic importance.

Next to the *Teredo Navalis* and *Xylotrya* (*Bankia*), the limnoria of the crustacean group is of the greatest economic importance. This animal has a flat body with fourteen segments and is about the size of a grain of rice. It has stout legs, some of which are equipped with claws like young lobsters. The eggs are carried on the abdomen of the female and the young, when born, are able to swim and walk as well as to bore. Although the rate of reproduction is much lower than in the teredo group, the proportion of young reaching maturity is much greater.

The limnoria chews the wood with its mandibles, making small galleries about $\frac{1}{16}$ in. in diameter and $\frac{1}{2}$ in. deep. In one specimen examined in San Francisco, there were from 200 to 240 burrows per square inch. It appears probable that the limnoria uses the excavated wood as food to a limited extent. On Fig. 4, *A* is a fragment of a Southern pine pile showing *Xylotrya* attack, cut between medium and low tide, after three years of service at Biloxi, Miss. *B* shows the results of limnoria on an untreated pile after two years of service at Boca Grande, Fla. *C* shows the results of limnoria and teredo action. The last specimen was secured in March, 1922, at Manhattan Beach, N. Y.

The sphæroma is another crustacean borer similar to the limnoria in its bodily structure and method of work. It is olive or reddish brown, marked with yellow, whereas the limnoria is greyish. This species reproduces in the same manner as the limnoria; there is, however, little knowledge of the life history of either species. The sphæroma is larger than the limnoria, and its burrows are frequently $\frac{1}{2}$ in. in diameter. Its activities are generally in the tidal plane, and it is not often found at the greater depths in which the limnoria and teredo work. This species does much less damage than the limnoria, but its activities are not confined to salt water.

The chelura, another species of the crustacean borer, is of less importance than the limnoria or sphæroma. Its work has the same appearance as that of the limnoria, and the two species are frequently found together. Thus far, the chelura has only been identified on the South Atlantic and Gulf Coasts.

Marine borers of one species or another exist in salt water practically all over the world, and there are some species which work in fresh water. They are of various sizes and differ as to their living requirements and capacity for destruction, but all of them, identified so far, are classified in either the molluscan or crustacean groups. The species of teredo living in the open

sea in ships bottoms, grows to be 6 ft. in length and 1 in. in diameter, whereas the *Teredo Navalis* is seldom more than ½ in. in diameter and 8 in. long. The *Xylotrya* (*Bankia*) is sometimes ¾ in. in diameter and 3 ft. long.

The living requirements of the different species are not known with certainty. It is thought that the *Xylotrya* (*Bankia*) requires a salinity of at least 20 parts per thousand and will not work effectively where there is considerable pollution by sewage or industrial wastes, although recent reports from Seattle, Wash., seem to indicate that it may have greater resistance to pollution than has been supposed.

According to the older European reports, it appeared that the *Teredo Navalis* would not live in water with a salinity less than 9 parts per thousand, but the exhaustive experiments, under the direction of the San Francisco Bay Marine Piling Committee indicate that this species will maintain a fairly active life with a salinity as low as 4 or 5 parts per thousand, and this result has been confirmed by experiments in the biological laboratory at Plymouth, England. It has also been demonstrated that this species will live at least 28 days in fresh water, although it will not work under this condition. If salt water is supplied after this 28-day period, the animal will open its pallets, extend its syphons and begin work. In fresh running water, it does not seem to survive much longer than a week. Experiments in the San Francisco Laboratory have also shown that the *Teredo Navalis* will live and work with full efficiency in water so polluted by sewage that there is no free oxygen, and putrefaction is taking place. These experiments are corroborated by the activity of this species in Oakland Creek which is very foul, and its immunity from the effect of industrial wastes is shown by its destruction of the wharves of the Standard and Shell Oil Companies where refinery wastes were discharged into the water which, with the piles, was covered by a scum of oil. The wharves of the Shelby Smelter Company, under which there was a discharge of copper sulphate, were also destroyed.

The crustacean borers have not been thoroughly studied, but it seems probable that the limnoria requires a fairly high salinity and is not seriously affected by pollution. The sphæroma is likewise little affected by pollution, but it will live and work in either salt or fresh water. The requirements of the chelura are little known. Fig. 5 shows the typical appearance of piles attacked by limnoria.

The distribution of the more common borers, as far as is known, is as follows:

The *Xylotrya* (*Bankia fimbriata*) is found from Nova Scotia to Florida, throughout the Gulf of Mexico, and from California to Alaska.

The *Teredo Navalis* is reported by many writers on all coasts, but many reports are of doubtful accuracy. It has been identified in the vicinity of New York City and San Francisco, and in Europe, from Norway to Italy, except in the Baltic Sea east of Kiel. Some species exist in the Eastern Mediterranean and Black Sea. It is reported that ships on the blockade of Sebastopol during the Crimean War, were damaged and some of them sunk by the *Teredo Navalis*.

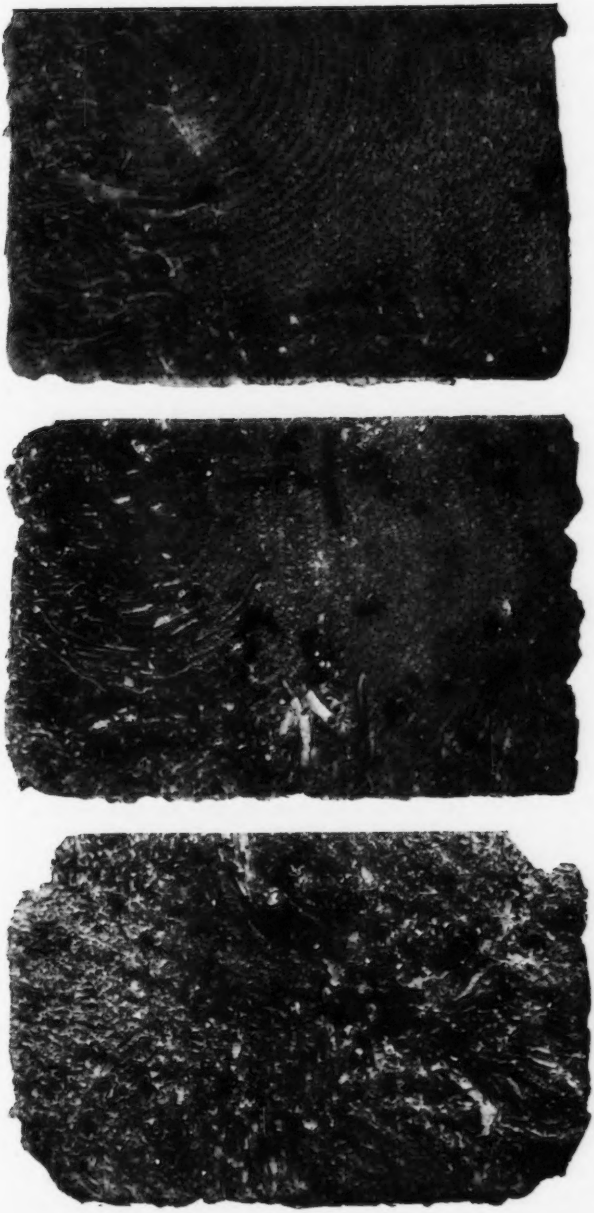

FIG. 6.—ACTION OF TEREDO ON DOUGLAS FIR TEST PIECE.

The limnoria is found on all the coasts of North America and in practically the same locations as the *Teredo Navalis* in Europe. Its maximum activity occurs near the North Cape as well as at points farther south.

The limits of the sphæroma are not absolutely defined, but it seems to be of general distribution.

The chelura has been identified so far only in the South Atlantic and Gulf of Mexico.

Some harbors seem to be immune from the activities of some or all of the borers, and the reasons for this immunity are among those facts which the National Research Council is trying to develop by its investigation. Boston Harbor, for example, has been generally immune from teredo attack and although limnoria is present, no great damage has been done. In the paper presented by Mr. Bayley in 1874, previously mentioned, it is stated that a marked reduction in the activity of teredo had taken place in the Port of New York, in the three or four preceding years. It was thought by Mr. Bayley that this was due to an increase in the sewage pollution. If this was the correct explanation, it is probable that the *Xylotrya* (*Bankia*) was the species present, as it has been demonstrated that the *Teredo Navalis* lives in water with a much higher sewage content than that of New York Harbor. The activities of the teredo may be influenced by many other factors, about which nothing is known at present.

The rate of destruction by the molluscan borers does not seem to be greatly affected by the different kinds of timber in common use for construction purposes in the United States.

Fig. 6 shows the destructive action of the *Teredo Navalis* on a 6 by 8-in. Douglas fir test piece planted on July 1, 1920, at the Southern Pacific Wharf at Port Costa, Calif. The first larvæ were discovered on August 4, and the timber was removed on December 8, 1920. Section *a* was 10 ft. 2 in., Section *b* was 6 ft. 6 in., and Section *c* was 6 in., above the mud-line. The contrast between inshore (right) and offshore (left) in the intensity of attack may be noted. The speaker had a wharf completely destroyed by *Xylotrya* in 18 months in Resurrection Bay, Alaska. W. H. Courtenay, M. Am. Soc. C. E., reports that a platform for carrying test pieces under a wharf at Pensacola, Fla., was destroyed in 30 days. Under favorable conditions, either the *Teredo Navalis* or the *Xylotrya* will destroy a 14-in. pile in 3 months.

The rate of destruction by the crustacean group is lower than that by the *Mollusca*. In waters where the limnoria is active, it seldom destroys a yellow pine or fir pile in less than a year.

The outbreak in San Francisco Bay is fully described in the valuable reports of the San Francisco Bay Marine Piling Committee issued in 1921 and 1922. As history repeats itself, one may reasonably assume that similar outbreaks may occur at other places formerly immune.

Borers, probably the *Xylotrya* (*Bankia*), had existed in the Lower Bay for many years, but were unknown in the vicinity of Mare Island and Carquinez Straits. The *Teredo Navalis* was first identified in 1914 in the long pile dikes

protecting the channel to the Mare Island Navy Yard, and the borers apparently spread slowly through these dikes in the following years. Their activities became noticeable at other points in 1919 and, by the end of 1920, they had destroyed many structures near Mare Island and in Carquinez Straits, over a distance of about 8 miles, and had been found at Antioch, 25 miles up the Sacramento River. There is a strong tidal current through Carquinez Straits, which undoubtedly aided materially in the distribution of the larvæ.

Previous trouble with borers had not been experienced at the Mare Island Navy Yard and, consequently, the Navy Department had started to build a pile highway bridge between Mare Island and Vallejo, using unprotected timber. A few days before this bridge was to be opened for traffic, it was discovered that a number of the piles were eaten off and hanging from the drift-bolts. It was necessary to re-drive the entire structure with creosoted piles. Engineers for corporations owning structures in this territory estimate that the cost of repairs of damage caused by borers to the end of 1921 was more than $15 000 000. The history of this attack clearly shows that previous immunity does not justify the assumption that such immunity is permanent. Eternal vigilance is the price of safety.

Since the beginning of history, efforts have been made to protect structures from these organisms. The Phœnicians and the Vikings charred their ships and painted them with pitch, and the galleys of Troy were sheathed with lead. The writer has recently received letters from inventors and others who think they have discovered something new. Frequently, investigation shows that these "new" ideas have been tried by the Ancients. It is necessary, therefore, that harbor engineers seeking to protect structures from the ravages of borers should thoroughly familiarize themselves with the history of the borers and the attempts to secure protection from them.

The Forest Products Laboratory of the U. S. Department of Agriculture collected a great amount of data on methods of protection and, in 1913, an exhaustive report was prepared by Mr. A. K. Armstrong, which, unfortunately, was not published. The Committee on Marine Piling Investigations of the National Research Council is continuing this study and hopes to publish the results soon. This report divides protective methods into three general classes: The first includes reports on the charring of timber, the use of built-up piles and of unbarked piles. None of these methods has any permanent value. The second includes protection by mechanical means and the third by impregnation with various chemicals.

The second method is subdivided into painting or coating with paint compounds, protection by metal sheathing, earthenware pipe, pipe manufactured of other material, concrete, or an elastic or supposedly elastic coating. On Fig. 7, *A* is a section of a Douglas fir pile taken from Seattle Harbor after 4 years of service. This pile was creosoted, but very imperfectly. *B* shows a section, 3 ft. above the mud-line, of an untreated Douglas fir pile, after 1½ years of service at Vancouver, B. C., Canada. The pile had tight bark when driven. *C* shows a section of an untreated Douglas fire pile, 6 ft. above the mud-line, after 1 year of service at Vancouver. Surface treatment with paint

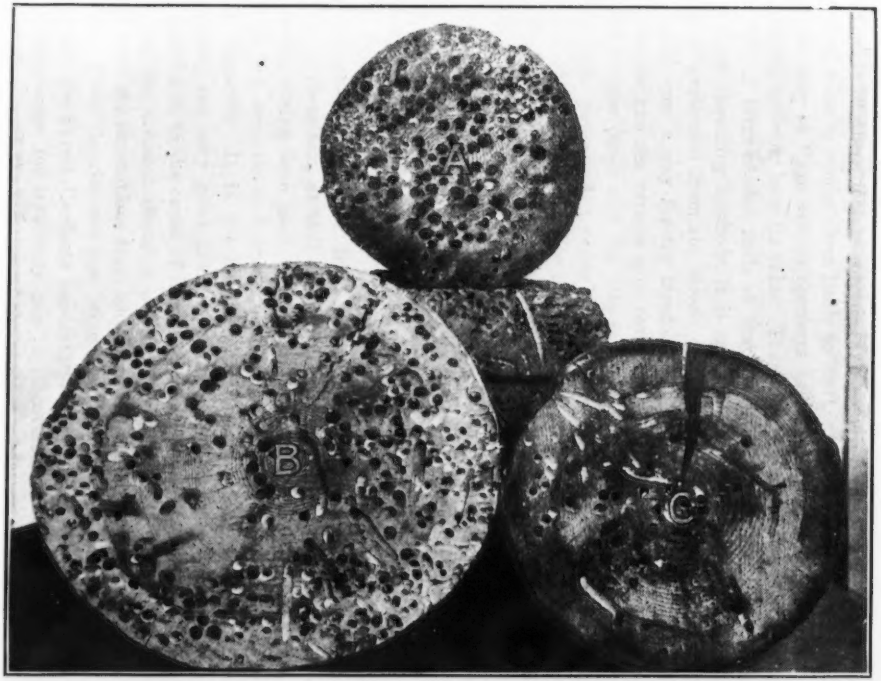

FIG. 7.—DOUGLAS FIR PILING AFTER FOUR YEARS' SERVICE.

or other material is damaged or destroyed by checking from rough handling during construction or by the abrasion or impact of floating material after it is in place. This method, although it may give temporary protection, is not permanent.

The metals used for sheathing have generally been lead, rolled iron, copper, zinc, several alloy metals, cast iron, and the process of nailing developed in Holland. All these metals corrode, and some of them, like copper, are of sufficient value to render them liable to theft. Any of these sheathings is efficient as long as there are no openings in the coating, but as soon as holes appear, the covering loses its value. The nailing process consists of driving the pile full of large-headed nails so that the surface is covered by the heads. Like other sheathing methods, it is expensive and although reported to have value as protection from the teredo, the limnoria is reported to dig out the nails and open a way for the teredo.

Concrete and the various pipe coverings are effective as long as no breaks in the surface occur and the pile is covered from the mud-line to a little above high water. A number of concrete coatings have failed, some on account of defective concrete and others because the mud-line was lowered and the borers cut off the pile between the new mud-line and the bottom of the covering.

The process of wrapping piles with a fabric impregnated with asphalt or similar material results in a pile that will resist attack until an opening is made in the coating. It is difficult to drive a pile without breaking such a coating and still more difficult to prevent damage by floating objects after it is driven.

Impregnation has been tried, many metallic salts and other supposedly poisonous chemicals, as well as creosote and mixtures of creosote and other materials, having been used. Thus far, creosote seems to give the best protection, but creosote is a trade name and does not indicate a product of fixed character. It is not known what constituent or fraction gives the protection, nor why good creosote protects timber for a time. There are two theories as to the cause of immunity from attack of some creosoted piles, one that the creosote contains a poison and the other that there is some constituent the emanations from which prevent the larvæ from landing on the timber. These theories are now being studied at two or three college laboratories and the Forest Products Laboratory.

If the reason for immunity can be discovered, a distinct step will have been made toward the solution of the problem as far as creosote is concerned. Those who believe in the inhibition theory, point to the fact that the teredo will bore freely in creosoted timber after it reaches a little size and that the martesia does not seem to be affected by it.

Some structures built with creosoted piles have had a life of 30 years or more in badly infested water, but such cases are rare. Many structures have had short life when both the creosote and the treatment were good, but the surface was damaged in construction. Careless handling of creosoted piles is probably responsible for a large number of failures.

An investigation of the resistance of various timbers was also made by the Forest Products Laboratory. It was not found that any indigenous woods would resist borer action, except, perhaps, Palmetto and some of its relatives. These timbers have little strength and decay rapidly above water level, so the fact that they resist borers is of little importance from the construction standpoint. A number of foreign timbers, principally from the Tropics, are reported to withstand attack, but great confusion exists as to the botanical identification of the species and it is difficult to obtain facts.

The Greenheart of Demarara is shown, by many reports from foreign harbors, to have long life, whereas others report its failure after a few years of service. It was used in the lock-gate sills and similar places in the Panama Canal, but was a failure and has been removed. Many reports regarding Australian turpentine wood are favorable. A small quantity of this wood was used in a wharf at Victoria, B. C., and has given excellent results for about 8 years. A number of favorable reports have also been received from the British Colonial harbors. There are also a few unfavorable reports. In regard to experience with certain kinds of Eucalyptus, it may be stated that the report mentioned does not indicate that Eucalyptus is immune from attack.

The Committee on Marine Piling Investigations of the National Research Council, with the assistance of Engineering Foundation and the co-operation of the various Government departments and the owners of water-front property, is endeavoring to determine the biological and chemical factors of the problem. It is planned, first, to discover what species exist and where; what the salinity, temperature, oxygen content, and hydrogen ion concentration are, and their effect on the different species of borers. With the assistance of Government, university, and commercial laboratories, the Committee is trying to discover why one creosote protects and another does not. The possibility of securing protection by the use of other substances is also being studied. It is hoped that, when these investigations are completed, it will be possible to draw a specification for creosote that will permit the removal of all constituents not necessary for protection and of value for other purposes, and to leave a substance that will be efficient.

The Committee is also making a study of substitutes for timber construction with the hope of issuing reports which will be of economic value to all builders and owners of water-front structures.

THE ST. MAURICE RIVER FLOW REGULATION

By O. LeFebvre,* Esq.

In 1912, the Government of the Province of Quebec adopted the policy of regulating the flow of the rivers of the Province, where storage reservoirs could be economically built and the stored water used for power purposes. The St. Maurice River was the first stream on which this policy was practiced.

The St. Maurice River rises in a series of lakes about 1 300 ft. above mean sea level, and flows from the northwest across the Laurentian Mountains into the St. Lawrence at Three Rivers. The river is about 367 miles long, has a drainage area of 17 000 sq. miles, and is broken by many falls and rapids, the principal ones of which are the following:

Name.	Height, in feet.
Les Forges	12
La Gabelle	10
Les Grès	44
Shawinigan	150
Grand 'Mère	78
La Tuque	88
Rapid Blanc	212
Rapid des Cœurs	93
Rapid Allard	45

The Shawinigan and Grand 'Mère Falls are fully developed, and that at La Tuque is partly utilized. It is expected that the falls at Les Grès and La Gabelle will be developed shortly.

Timber is the principal resource on the St. Maurice. Logs are floated down the streams to the main river, and down the latter to the different mills. The number of logs cut has been steadily on the increase until 1921.

Natural Flow of the River.—The flow of the river has been recorded at Shawinigan by the Shawinigan Water and Power Company, and daily discharge records are available from 1900 to date. The average low-water discharge is 6 000 sec-ft. The lowest discharge recorded is 5 200 sec-ft. for about a week in March, 1901, and the highest, which was recorded May 16th, 1904, was 166 000 sec-ft.

The average depth of yearly run-off from the water-shed at Shawinigan for the period 1900-21 was 21.6 in., the maximum being 26.9 in., in 1907-08, and the minimum, 15.33 in., in 1906.

Power.—The power at Shawinigan is generated under a head of 150 ft. and the low-water capacity of the plant was 82 000 continuous h. p. The machinery was designed for the discharge available during eight months of the year and the Company was disposing of the power as primary and secondary power. The total power possibilities on the river at natural low-water periods was estimated at 40 000 continuous h. p., which could be almost doubled if

* Chf. Engr., The Quebec Streams Comm., Montreal, Que., Canada.

secondary power was used, but secondary power is seldom satisfactory to the customer and must be disposed of at a low price. As the demand increases, the companies on the St. Maurice look for additional power by a more regulated flow of the river.

In 1909, the power and lumbering interests organized the St. Maurice Hydraulic Company which was authorized by the Government to complete certain storage schemes on the Manouane River. Three small dams were constructed from 1909 to 1911 and the reservoirs thus created have a total capacity of 590 sq. mile-ft. The water from these reservoirs was used during summer low water and during the winter. The minimum flow at Shawinigan was thereby raised to nearly 8 000 sec-ft.

These Manouane reservoirs proved the feasibility of obtaining water from reservoirs 200 miles from the generating plant, even under most severe winter conditions. In 1912, the St. Maurice Hydraulic Company applied to the Legislature for authority to carry out storage on a much larger scale in the series of lakes which form the upper reaches of the St. Maurice River. The Quebec Government decided, however, that it would be better policy for the Province to complete the scheme, and the Quebec Streams Commission, therefore, was asked to investigate and report on the possibilities of storage in the upper lakes.

Two alternative schemes were considered: Five small dams, each controlling a series of lakes and giving partial control, or one big dam giving complete control. The latter scheme was favored and recommended by the Commission.

It was found that by building a dam near the head of La Loutre Falls, and raising the water 47 ft. above natural low water, the capacity of the reservoir would be 5 722 sq. mile-ft. The area of the water-shed was 3 650 sq. miles, and the proposed reservoir would have capacity for 19 in. of run-off from the basin.

After investigations at the site, plans were prepared and several types of dams were considered. The gravity type was recommended by Edward Wegmann, M. Am. Soc. C. E.

The design provided for 50 000 lb. per lin. ft. of ice pressure, acting at the spillway level. No ice has formed opposite the gate section within 50 ft. from the dam, and it is doubtful whether any great ice thrust has been exerted against the structure.

The dam is 240 miles from the St. Lawrence River and controls the water from a drainage area of 3 650 sq. miles. The aggregate area of the lakes forming the reservoir was 209 sq. miles under natural conditions. To-day, they form one single body of water with an area of more than 300 sq. miles.

The dam was completed in December, 1917, and has been operated to regulate the flow of the St. Maurice at 12 000 sec-ft. at Shawinigan since January 1, 1918.

Additional Power.—The benefits to be derived from regulation were calculated from the flow curve of 1906, which was the lowest year for the period, 1900 to 1912. A duration curve was made and the water necessary to make up the deficit for a minimum flow of 12 000 sec-ft. was calculated. Distributed

uniformly over the whole year, the power increase at Shawinigan totals 32 250 h. p.-years. At Grand 'Mère, where the water is being used under a head of 75 ft., the power increase is one-half that at Shawinigan.

In order to ascertain whether the quantity of water available in the Gouin Reservoir would be sufficient for a regulation of 12 000 sec-ft. at Shawinigan, investigations have been conducted since the latter part of April, 1913, when flow records were kept at the site of the Gouin Dam. The quantity of water measured at the dam site was taken as the supply from the dam and that required at Shawinigan to increase the flow to 12 000 sec-ft. was taken as the demand.

As it requires from 10 to 12 days for the water from the reservoir to reach Shawinigan the calculations were based on a loss of 25% from evaporation and on other losses. Similar calculations were made for a regulation to 14 000 sec-ft. The curves show that such regulation is possible, but if a loss of 25% should occur, the reservoir would not be large enough. Since the dam has been in operation, it has been noted that the loss is negligible, being only about 5% in the winter.

Discharge Control.—The discharge of the river is controlled at three points, namely, at Weymontachingue, 50 miles below the dam, at La Tuque, 155 miles from the dam, and at Shawinigan. The water level at Weymontachingue and at La Tuque is recorded daily and the information wired to the office of the Quebec Streams Commission. Similar information is obtained from the Shawinigan Water and Power Company regarding the conditions at Shawinigan and Grand 'Mère. The points of control are also provided with rain gauges. In this way, a good idea may be gained as to the period it will be necessary to draw on the storage.

Ground Storage.—By raising the water 40 ft. above natural high water at La Loutre, the different lakes form one body of water, more than 300 sq. miles in area. As a great deal of the area covered is pervious, much ground storage must take place. The natural run-off, as a rule, is a minimum in March. Before the water was raised, the average for the winter months of three years was as follows:

January	291 sq. mile-ft.
February	219 " " "
March	215 " " "

Since the reservoir has been operated, the run-off in March and February is much larger than in previous years, as shown by the comparison given in Table 7. This cannot be explained otherwise than by ground storage.

TABLE 7.

Months.	1919.	1920.	Average of 3 years before operations began.
March.....	450 sq. mile-ft.	785 sq. mile-ft.	215 sq. mile-ft.
February	284 "	751 "	219 "

Land Clearing.—The area flooded by the reservoir has been estimated at 100 sq. miles, most of which is forest. This flooded area was not cleared on account of the cost, but it is not expected that much of the floating dead wood will reach the dam.

Manouane Dams.—Mention has been made of the three dams on the Manouane River. These dams have been acquired by the Commission and are being operated together with the Gouin Dam for the regulation of the St. Maurice. The dams are of the ordinary wooden crib type, filled with stone, their sluice openings being controlled by stop-logs. The combined capacity of the reservoirs formed is nearly 590 sq. mile-ft. The combined drainage area is 1 250 sq. miles. The supply of water from the basin is, therefore, much larger than the capacity of the three reservoirs, which overflow in the spring and are generally emptied during the dry summer months.

Cost.—The cost of the whole work was $2 500 000, or $400 per sq. mile-ft. of water. The yearly revenue is at present $215 000, which will be increased when new water power is developed.

This regulation work has been a success and, the amount of power now generated on the St. Maurice River is almost 500 000 h.p. Nearly 500 000 additional h.p. could be developed. It is believed that these works will make the St. Maurice River one of the most important sources of water-power on this Continent.

SHORE PROTECTION AND HARBOR DEVELOPMENT WORK ON THE NEW ENGLAND COAST.

By Frank W. Hodgdon,* M. Am. Soc. C. E.

The New England coast consists of ledges, sand beaches, and bluffs composed of glacial drift, and the beaches and bluffs are gradually washing away.

The sea acts in two ways: First, sand and gravel, stirred up by the waves, are carried over the top of the beach, thus filling the low land back of it and forcing the shore line inland.

Where the land back of the beach is high, the waves drift the material along the shore until a low beach with low land back of it is reached. Here, the material is either washed over the beach on to the low land, or gradually drifts into the sea and forms shoals, as at the southeasterly part of Cape Cod Bay where they extend more than a mile from the shore.

Many different forms of protective work have been used in the endeavor to prevent further erosion. In some places, timber bulkheads were built at or above the high-water mark. A number have been back-filled, but in almost every case the timber structures have been either broken down or undermined. The large islands which form much of the protection to Boston Harbor, were early protected with heavy granite sea-walls and rip-rap by the Federal Government.

In 1828, a wall was built to protect the headlands of Deer Island and, in 1843, one was built at Lovells Island. Walls were built later at the Brewster Islands. In 1871, walls were built at Point Allerton, Long, and Gallops Islands. These later walls on the outer shore are about at the high-water line and their foundations are about at mean sea level. The tidal range is about 9.5 ft. and the top of the wall is about 22.5 ft. above mean low water. The wall is 5 ft. thick at the top and 9 ft. at the base, with a footing 12.5 ft. wide. The face is of granite and the backing and footing are of concrete. Adjoining the wall at the level of its top a pavement, 15 ft. wide, of granite slabs has been placed on the fill to prevent wash from waves which break over the top. The beach in front of the wall is also protected with a rip-rap of granite grout. These walls, although requiring repairs from time to time, have effectively protected the cliffs from erosion.

At the bluffs in Scituate and Chatham, the Commonwealth has deposited heavy granite grout from the high-water mark to 12 or 15 ft. above it. Sections of this protection at the Scituate Third Cliff have been in place for 14 years. At Chatham, at the bluffs in front of the lighthouses at East and West Chop, on Martha's Vineyard, ridges of stone have been placed about at high-water mark for a considerable distance on each side of the lighthouse. This has been an effective protection.

At Cotuit and Osterville, on the southerly shore of Massachusetts, facing Nantucket Sound, the bluff which is about 10 ft. high, is being eroded rapidly by the action of the sea. The owners have constructed timber bulkheads along the shore just above high water and, at intervals of 30 to 50 ft.,

* Chf. Engr., Div. of Waterways, Massachusetts Dept. of Public Works, Boston, Mass. Mr. Hodgdon died on January 26, 1923.

short timber spurs or jetties have been extended, which have prevented the sand from drifting along the beach, and a barrier has been formed, which has stopped the sea from making further inroads. These structures require constant attention as they are usually built of 2-in. plank spiked to 4-in. square stakes, the posts of the bulkhead being of cedar, 6 or 8 in. in diameter. This work, although costing considerable for upkeep, has been effective. The water in front of these bulkheads is shallow for ¼ or ½ mile. The range of the tide is generally less than 5 ft., and the waves are not heavy.

To protect the beaches at various points along the shore, walls with spur jetties from 50 to 100 ft. apart, have been built of concrete. The walls are located on the crest of the beach or between the crest and the high-water mark and the jetties project 1 to 2 ft. above the level of the beach. These walls extend about 22 ft. above low water or 12 ft. above high water and are built with a lip projecting about 6 in. at the top to deflect the sea. On the Scituate shore, some of the first walls had no lip and extended only 18 to 20 ft. above mean low water. At this elevation, the sea broke over the top and in places, large quantities of sand and shingle were washed over the wall. The beach was thus reduced, enabling the sea to undermine the wall in places so that it collapsed. It has been rebuilt to the elevation of 22 ft. with a projecting lip.

The harbor improvements may be divided into two parts: The improvement and protection of the channels, and the construction of wharves and docks. In the larger harbors, the U. S. Government has enlarged and deepened the channels and protected the entrances.

Boston Harbor.—In Boston Harbor, the principal work has been the dredging of the channels and the removal of isolated rocks and extensive ledges. The material, which is mostly clay, gravel, hardpan, and rock, has been excavated largely with scoop dredges. At first, the excavated material was deposited in the harbor, but recently most of it has been dumped in deep water outside the harbor. Inside the harbor, a large quantity of material was used for filling at South and East Boston where the Commonwealth has undertaken large reclamation plans. There are three entrance channels in Boston Harbor. The original or southerly channel just south of Boston Light crosses the entrance of the harbor about at right angles to the direction of the current caused by the tide. It originally had a depth of about 18 ft. at low water and was partly obstructed by rock or large boulders which have been removed. This channel has been dredged to a depth of 27 ft. at mean low water, with a width of nearly 1 000 ft. The Broad Sound Channel, which was next opened, has a depth of 30 ft. and a width of 1 200 ft.

The third or northwesterly channel extends straight from the sea into President Roads and has a depth of 35 ft. at mean low water and a width of 1 500 ft. President Roads is a large area with a depth of water exceeding 40 ft. at low tide, into which these three channels lead. Extending from President Roads to the wharves at the city is a channel 35 ft. deep and 1 200 ft. wide, which originally was not more than 18 ft. deep at low tide. The excavation was mainly of silt and clay with some hardpan and considerable ledge, most of

the rock being slate. The character of the bottom of the harbor is such that there is very little shoaling caused by shifting material. The currents generally are less than 1½ miles per hour.

Leading to various points in the harbor are a number of subsidiary channels which have been dredged to depths ranging from 6 to 30 ft. at mean low water. In the inner harbor, a large number of wharves were constructed at an early date and until about 1870 were practically all owned by private individuals. Since that time, the Commonwealth has improved the flats at South Boston and, later, those at East Boston.

About 600 acres of flats extend from the shore of South Boston from ½ to 1 mile and about 2 miles in length from the city to Castle Island. This area has been filled by the Commonwealth and its grantors, mainly with material excavated from the harbor channels, and on it are the wharf terminals of the New York, New Haven and Hartford Railroad, and the Commonwealth Dry Dock, 1 200 ft. long, 35 ft. over the sill at low tide and 120 ft. wide in the entrance, which was built by the Commonwealth and sold to the United States Navy Department in 1919. Alongside this dock is the area sold to the United States Army on which the Army Base was erected at a cost of about $25 000 000. The Commonwealth Pier, which is used by the largest merchant ships, and the Fish Pier, on which is the greatest fish industry in the United States, are also located here.

The Commonwealth Pier is 1 200 ft. long and 400 ft. wide with a depth of 40 ft. in the slips at low tide, the mean range of tide being nearly 10 ft. The pier itself is constructed of a granite sea-wall, 16 ft. high, founded on piles which are cut off at mean low water. The area enclosed by this wall, which is 2 700 ft. long, is filled with material excavated from the docks. Outside the sea-wall is a pile platform, 50 ft. wide, covering the slope of the excavation from the bottom of the dock to the foundation of the sea-wall at low water. This slope, which is 1 : 1.5, is covered with rip-rap. On this, as a foundation, has been built a steel and concrete two-story shed with a heavy masonry front or head-house. On this pier, in addition to the spaces devoted to cargo, are accommodations for handling from 1 000 to 2 000 passengers at a time, with facilities for all the necessary examinations of the passengers and baggage. The passenger facilities are on the second floor, from which a viaduct leads to Summer Street.

The Fish Pier is a solid-fill wharf. The filling is retained by a granite wall, 41 ft. high, founded on rip-rap deposited in a trench in the bottom of the harbor. The water in the slips alongside is 23 ft. deep at mean low water. The pier is 1 200 ft. long and 300 ft. wide. The vessels lie up against the granite wall, on the face of which are oak fenders. The surface of the wharf outside the buildings is paved with granite blocks on a concrete base and the buildings are of concrete. In addition to the stores for handling fresh fish, a large cold storage plant has been built in which the surplus fish are stored awaiting a market.

The wharves at the New Haven Terminal are similar to the Commonwealth Pier, except that the floors of the sheds are of timber instead of

concrete and the sheds are of wood instead of steel and concrete. All piles of the platforms in both terminals are of oak.

At the Army Base, the piles of the wharf, which support a heavy concrete floor, are of pine. The buildings are of concrete and steel. Those on the solid portions are supported on concrete cylinders sunk into the clay, and the two-story sheds on the wharf are on the pine pile foundations. The sheds on the wharf are connected with the building on the solid portion by bridges over the driveway and tracks between the buildings. This wharf is equipped with four cranes of the semi-portal bridge type, each of which has a capacity of 4 tons at a distance of 29 ft. from the face of the wharf.

The early wharves in Boston Harbor were built of stone-filled timber cribs enclosing areas which were filled with earth. Granite walls were used later in place of cribs and, in order to secure a greater depth of water alongside, the solid wharves were extended by building pile piers. In some cases, the granite walls were built on pile foundations. Some of the pile piers or platforms were built with timber floors, but, in others, the piles were capped near high-water level. Round poles were laid on the caps and covered with marsh sods. On this, gravel was filled to the level of the wharf which was 14 to 16 ft. above mean low water. The filling was held in at the face of the wharf by timber bulkheads tied back to the capping of the piles. Thus, the timber work and piles, except the bulkheads which retained the filling, were kept wet and did not decay, and the cost of maintenance was small. A few wharves were built with granite walls extending about 20 ft. below low water, but most of the walls were founded on hard bottom or on piles at about low-water level,

Other Harbors.—Massachusetts has a number of small harbors which have been improved by dredging the channels and anchorage basins and by building breakwaters and jetties to protect their entrances. The principal work which was undertaken by the Federal Government was the construction of a harbor of refuge at Cape Ann, where a heavy granite breakwater was built to enclose a large deep-water bay, known as Sandy Bay, at the outer end of the Cape. Up to low water, the breakwater consists of a ridge of large blocks of granite quarry grout. The superstructure consists of a facing of large split dimension stone backed up with quarry grout. About 6 000 ft. of the substructure has been built and about 900 ft. of the superstructure.

The slope of the faces of the substructure is 1 : 2 and of the superstructure 1 : 1. The facing of the superstructure consists of blocks weighing more than 20 tons each. The top of the finished breakwater is 22 ft. above mean low water and is 20 ft. wide. As the stones are somewhat displaced in heavy weather, the maintenance of the superstructure may be costly. Owing to changes in means of navigation, there is now much less need of a breakwater in this locality, and it is probable that this one will not be completed soon.

On the sandy shores like those at the mouth of the Merrimac River, stone jetties have been built to confine the current and direct it so that a channel will be scoured through the bar. To confine the current and prevent the waves from washing sand through the jetty into the channel, these jetties have been built of a facing of granite quarry grout with a core of chip

stone. They extend out to deep water, in order that the sand scoured out will be deposited there.

The Commonwealth has built a number of breakwaters to protect small harbors, such as Apponaganset near New Bedford and at Vineyard Haven on Martha's Vineyard. These breakwaters are ridges of granite quarry grout 5 ft. wide on top, with side slopes of 1 : 1.5, the top being from 4 to 5 ft. above high water. These breakwaters protect anchorage areas used by small boats and yachts.

Because of insufficient funds, most of the work done by the Commonwealth cannot be completed at one time and, in a number of cases, it has been practically abandoned after being partly completed. This has given an opportunity to study the effect of the work in various stages.

In some cases, channels constructed through sandy beaches, as at the easterly end of the Cape Cod Canal, have a long jetty on the side of the opening from which the sand drifts, and a short jetty on the opposite side. The sand is thus prevented from entering the channel, and the beach back of the jetty is built up.

In some instances, the funds were small, and a jetty was built on the leeward side of the opening, in which case, the current was relied on to scour a channel. This has resulted in a narrow channel through the beach, which to the leeward has built out and up, and shoals have formed in front of the channel. The practice of placing the jetty on the windward side of the opening and dredging the channel has been more satisfactory.

Cape Cod Canal.—The largest private undertaking in Massachusetts was the construction of the Cape Cod Canal. This project had been under consideration almost since the settlement of the country. Surveys were made from time to time up to 1860, when an exhaustive report was presented to the State Legislature. From 1870 to 1889, many charters were granted by Massachusetts to build canals from Buzzards Bay to Barnstable Bay and, about 1880, two attempts were made to excavate a canal, both of which failed for lack of financial support. In 1889, the Boston, Cape Cod, and New York Canal Company was incorporated, which later secured the co-operation of Mr. August Belmont of New York City. On August 19th, 1907, the construction of a canal was begun, which was opened to traffic on July 29th, 1914.

The canal is 8 miles long, has a depth of 25 ft. at mean low water, a bottom width of 100 ft., and side slopes of 1:2 in the main part of the canal. The bottom width of the easterly approach channel is 300 ft. and that of the westerly, or Buzzards Bay, approach is 150 ft. The sides of the canal are rip-rapped from 6 ft. below mean low water to 6 ft. above mean high water to protect the banks from the wash of passing vessels.

The canal is spanned by three draw-bridges having openings 140 ft. wide. The two highway bridges have a clearance of 30 ft. above extreme high water, that of the railroad bridge being 2.5 ft. The canal is electrically lighted throughout, and the draws in the bridges are operated by electricity.

The tidal currents in the canal are quite strong, the mean tidal range at the easterly end being 9.4 ft. and at the westerly end, 4.2 ft. High water

at the westerly end is about three hours later than at the easterly end so that the direction of flow changes quickly. The velocity of the current is from 3 to 5 miles per hour in the narrow section.

The easterly entrance is protected by a stone jetty about 3 000 ft. long on the northerly side. The westerly end is so well protected at the head of Buzzards Bay that no jetties were required, but a channel about 6 miles long had to be dredged in the Bay to reach deep water, thus making the distance from deep water in Barnstable Bay to deep water in Buzzards Bay about 14 miles.

At each end of the canal, where the section widens, shoals occur, which are removed by dredging. That part of the canal above tide level was largely excavated by steam shovels and drag-line scrapers. The lower part was excavated mostly by dipper dredges as the material contained many boulders. This material was dumped in deep water outside the canal. A small part was excavated by hydraulic dredges. This material was dumped on the marshes and other low lands on the banks of the canal.

Because of the swift current, the advisability of placing a lock in the canal was discussed. It was decided, however, not to install it, and the canal is being operated successfully.

DIFFICULT FOUNDATION PROBLEMS FOR PISCATAQUA BRIDGE AT PORTSMOUTH, N. H.

By J. W. Rollins, Jr.,* M. Am. Soc. C. E.

The Piscataqua River is not very long, but has great possibilities for trouble. The tidal flow through the 900-ft. channel at Portsmouth is very great, the ebb tide having at times a velocity of 8 miles per hour.

In 1917, the New Hampshire Legislature authorized the appointment of a commission to investigate the feasibility of the construction of a highway bridge across the river.

The Commission made a favorable report to the Legislature of 1919, and Governor John H. Bartlett of New Hampshire, advocated the construction of a bridge in accordance with the report. The Legislature appropriated $500 000 for its share of the cost of the bridge. The Maine Legislature of 1919 appropriated $500 000 for the work, and the Federal Government was also induced to appropriate $500 000.

Under the legislation enacted, a new commission was organized consisting of Secretary of the Navy Daniels, Governor John H. Bartlett, of New Hampshire, and Governor Carl E. Milliken, of Maine. Each of the Commissioners appointed an engineer to represent him, Secretary Daniels appointing Commander E. H. Brownell, U. S. N., M. Am. Soc. C. E.; Governor Bartlett, W. A. Grover, M. Am. Soc. C. E. of Dover, N. H.; and Governor Milliken, Mr. Lewis B. Jones, Bridge Engineer of the Maine Highway Commission. Mr. Jones was killed later in an elevator accident in Portsmouth, and Walter H. Norris, Assoc. M. Am. Soc. C. E., Bridge Engineer of the Maine Central Railroad, was appointed to take his place.

The Board of Engineers decided that the Portsmouth end of the bridge should be at Daniel and State Streets, and that it should cross the river at approximately right angles to the Kittery side, on Badgers Island. In September and October, 1919, investigations were made of the bottom of the river at the selected site, and this work was continued in May, June, and July, 1920.

Owing to the contour of the channel, the flood tide is on the Kittery side of the river, and the ebb tide on the Portsmouth side. These tides, acting in different channels, form great eddies the force of which cannot be estimated. The normal rise and fall of the tide is 9 ft., and this may be greatly affected by heavy winds.

The river bottom is covered with a layer of cobble-stones and gravel under which is a stratum of soft clay or mud, 3 to 10 ft. thick; next, there is a layer of hardpan from 6 to 10 ft. thick, overlying rock. The hardpan is so dense that a 5-ton orange-peel bucket would not touch it, and in the excavation in caissons it had to be loosened with pneumatic hammers.

The borings for the piers and abutments were made with drills, by wash-borings, and with well drills, the latter being used for the final determination

* Pres., Holbrook, Cabot and Rollins Corporation, Boston, Mass.

of the piers. The borings and soundings for the Portsmouth Abutment and the North Pier were close to actual conditions as determined by excavation, the North Pier being on rock at Elevation — 80.

On September 14, 1920, proposals were asked for the construction of the foundations and superstructure, in two separate bids. The two bids exceeded the amount available, $1 500 000, and the contracts were not awarded.

The original plans called for piers about 100 ft. long, with large sloping ice-breakers on the up-stream end, with a double Strauss lift bridge of 300 ft. span. As the authorities were anxious to complete the bridge, further studies were made to reduce the cost. A Waddell lift span was substituted for the Strauss lift, and the piers were re-designed and made symmetrical by omitting the ice-breaker. The result of these studies was that contracts were let, the substructure being awarded to the Holbrook, Cabot and Rollins Corporation, and the superstructure to the American Bridge Company. The work was awarded in November, 1920, and the speaker's firm began immediately to get plant and material on the site.

The great problem on this job was the moorings and anchors. No information as to the force of tides or water could be found, so the opinions of shipbuilders were obtained. The result of these inquiries was that a force of 80 tons might result from the worst tidal condition. No anchors would hold against such a force; therefore, for the main up-stream and down-stream anchors, cribs about 20 ft. square and 15 ft. high were built and filled with gravel.

The cables used were of galvanized plow steel, 2½ in. in diameter, having a breaking strength of 200 tons. For the side anchors, two 40-ft. concrete piles, weighing 10 tons each, were used, with 1½-in. steel cables. Each anchor had two cables to the caisson, one fastened to the concrete air caisson, the other at the top of the first set of caisson sides, making a total of twelve cables.

The general design of the caisson was a concrete air chamber, 27 by 75 ft., with a 7-ft. clearance. The walls were 5 ft. above the deck of the chamber, and, above that, regular wooden caisson side construction was used. The caissons were built on shore, where the launching space was very narrow and the water only 9 ft. deep at low tide. The launchways were placed on a grade of 2 in. to 1 ft., and it was planned to launch the caisson sidewise.

As no one seemed to know how the caisson would behave if it was launched with the 7-ft. air chamber open, it was decided to plank it solid across the bottom. No special provision for water-tightness was made, except to use matched planking.

The launchway had four double lines of 12 by 12-in. hard pine timbers as fixed ways, with a double set of 12 by 12-in. hard pine timbers as sliding ways. The fixed ways were spaced 4 in. apart, and the movable ways had a 4-in. guide bolted between them, thus forming a fixed guide to keep the caisson straight. The fixed and movable ways were bolted together with 4 by 12-in. splices on the inshore end. The caisson was launched by cutting these 4 by 12-in. strips.

The concrete air chambers were designed as the foundations of the piers, and on account of the great depth of the water, the relation between the mass of masonry in the pier and the cubic area of the caisson, was very close. For

this reason, it was not considered safe to build the piers solid above the roof of the air chamber designed to carry the hydrostatic pressure to the full depth of water at the pier site. Consequently, the piers were built with side-walls 5 ft. thick at the bottom and 3 ft. thick at Elevation — 80, with three lateral cross-walls and one longitudinal wall in the center. Excessive pressure on the caisson sides was avoided with this distribution of concrete. This form of construction later proved to be a great aid in sinking the caissons. After some experiments, the caissons were built to their full height, 66 ft. above the concrete. They were loaded to draw 40 ft. of water before being towed to the bridge site.

It was decided to build the North Pier first, owing to its more favorable position as to depth of water and tidal current. At this pier, the ledge was at Elevation ± 25 at the high corner and Elevation + 18 at the low corner, and was overlaid by 8 to 12 ft. of clay, with some hardpan. This overburden was dredged to the hardpan, about 3 ft. above the ledge. The caisson for this pier was built with one set of caisson sides, 22 ft. above the concrete air chamber. It was loaded to draw about 25 ft. of water and towed to the site.

The northerly side anchorages were on the ledge of Badgers Island, whereas all the others were crib or concrete anchors in the river. The flood tide struck the caisson about at right angles to its down-stream northerly side. No great strain was anticipated for the side anchors, as the ebb tide apparently was clear of the caisson. However, it was soon noted that the direction and force of the ebb tide had to be considered. The caisson would rest peacefully for a long time, and then some great swirl or eddy would strike it, and send it inshore, dragging the 40-ton anchors on the river side. With the outside line slacked, the flood tide would send the caisson back, bringing up hard on the inshore cables fastened to the ledge.

With 2 000 tons moving and "bringing up" hard on the inshore cables, it was evident that something must give way, as the side cables were not fastened to the caisson in a manner to withstand these shocks. The caisson, therefore, was taken back to the wharf and another set of sides 22 ft. high were built. A second set of fastenings was also built in it, and a second trip to the site was made.

The second attempt to land the caisson brought the same troubles as the first. The eddies on the ebb tide carried away the outboard anchors, moving the caisson 50 ft. inshore and landing it on the bottom of the river. It was finally decided that the bottom of the river was the only safe place for it.

With a hollow caisson, it was possible to flood the pockets with water and keep it on the bottom, and then, at low tide, pump out the water in one pocket and place the concrete. When a greater depth of water was needed to float the caisson, it was moved at high tide out into the deeper water. When the walls were built to Elevation 80, and concrete sufficient to hold the caisson in its true position on the bottom had been placed, it was moved out at high tide, and then sunk by filling the pockets with water. On the following slack tide, all the lines were "hitched up" and, at the next high tide, the caisson was floated by pumping out the water, lined up, and sunk again in its true position, which was within 3 in. of the line. Afterward, the caisson was kept on the bottom and sunk to rock.

The Portsmouth Abutment was built at the same time as the North Pier. A pier design was substituted for the Kittery Abutment. It looked simple on the plan—a sloping foundation on rock at an angle of about 30°, the front edge being shown at Elevation 74. Steel sheeting was driven below Elevation 74, 5 ft. in front of the line of the foundation, and the excavation was begun. Trouble soon developed, as the rock "dropped off" almost perpendicularly in the middle of the coffer-dam.

The sheeting was undermined and then driven down to low water. The excavation was made with a bucket, a sand-pump, and divers. The ledge was finally cleaned over the greater part of the area. Concrete was deposited under water, the entire excavation being filled to the sheeting. The excavation having been sealed, the coffer-dam was unwatered after a supplementary wooden dam had been built from the steel sheeting. The masonry was finished after a delay of several weeks.

At the South Pier, the bottom of the river sloped from about 1 ft. to 8 ft., and the rock, according to the soundings and borings, was at Elevations 29 and 26 on the inshore side, and Elevations 23.7 and 19.8 on the outer side. It was intended, therefore, to land the caisson on rock at about Elevation 25. Meanwhile, all the soft material possible had been dredged and the site of the pier had been leveled at about Elevation 30; this meant that the inner side would be hardpan and the outer side, the original bottom, that is, soft material.

It was feared that the caisson, when landed, would either go out of level toward the river, or would slide out of position into the river. To avoid this, a windrow of crushed stone, about 3 ft. wide and 2 ft. higher than the hardpan bottom on the inside, was deposited along the outside edge. The caisson was towed to its site and sunk very near to position. On the next high tide, it was floated and pulled into a position 1 ft. inside of its true line. Within 24 hours after it had been landed, it had slid about 12 in. out into the river. It was again floated and placed 24 in. inshore and landed. It again moved about 12 in. and stopped. Rip-rap weighing 1 000 tons was then piled on the outside and no further movement took place. The water was pumped out and the concrete put in. The caisson was permanently landed about 8 in. out of position inshore.

The crushed stone kept the caisson about 1 ft. out of level inshore, until it was landed on hard bottom. At Elevation 26, the supposed rock level, no rock appeared. The sinking was continued to Elevation 20, and still no rock. The sides of the caisson were not high enough, and the shafting, locks, air, and other pipes, had to be built up.

The contract did not require excavation to rock, and it was contended that at Elevation 20, the foundation on hardpan was suitable. The caisson was then 19 ft. below the original bottom on the up-stream end, and 12 ft. on the down-stream end.

The excavation was continued, and the cutting edge sunk to Elevation 16, 10 ft. below the designed level. The rock was cleared off in places to Elevation 9. As this additional work was done under an air pressure of 40 lb., the cost was excessive, being about $3 000 per ft. However, the entire contract was finished in March, 1922, seven months ahead of requirements.

TESTS OF CONCRETE IN SEA WATER

By L. C. Wason,* M. Am. Soc. C. E.

In the summer of 1901, the writer was frequently at the Charlestown Navy Yard, and observed the building of Pier No. 1. The concrete, of which this pier was constructed, was mixed so dry that, when it was tamped in place, no water showed on the surface. In a few years, this pier showed serious defects, and the writer and his associates discussed with various engineers the cause of this early failure. Many reasons were advanced, but no conclusion was reached. This discussion was broadened through the technical press without obtaining a satisfactory answer, and it was finally decided to investigate the cause. After extended publicity and correspondence, a series of twenty-four test specimens, 16 in. sq. by 16 ft. long, were made of various qualities of cement. Three different proportions of cement, sand, and broken stone, and three different quantities of water were used. These specimens were made during the first two weeks of January, 1909, and were immersed in the sea at the Charlestown Navy Yard, in the last week of February, 1909.

They were suspended so that more than 3 ft. of each specimen at the top would seldom be wet and, presumably, never be immersed, whereas about 3½ ft. projected below mean low water, and, therefore, would never be uncovered.

The details of the making, the progress, and the reports of the condition of these specimens have been described in two pamphlets entitled, "Aberthaw Tests on Concrete in Sea Water", issued in 1914 and 1920, respectively, in a number of articles in the technical press, and most fully by R. E. Bakenhus, M. Am. Soc. C. E.† Reference is made to these sources for full details. Only such extracts from those data will be given as are necessary to make this paper intelligible.

After 13¼ years of study of these specimens, the writer believes it is possible to make some tentative deductions on the cause of failure and suggestions for design so as to make future structures as nearly as possible proof against disintegration by sea water.

The conditions in Boston Harbor are probably as severe as in any harbor of the United States. The specimens are subjected to considerable tide run, attacked by waves, abrasion from floating objects, freezing during severe winters, and attack from impurities, chemical or otherwise, present in sea water.

In April, 1914, the Navy Department put into commission fuel-oil pipes adjoining these specimens. Oil spilled on the sea has heavily coated them from near their tops to low tide. The writer believes this coating retards the action by the sea water and, therefore, will lengthen the time required for this test, which, however, will not destroy its value.

At low tide, on May 22, 1922, the writer made an examination of the specimens. No appreciable change could be observed from the condition as

* Pres., Aberthaw Constr. Co., Boston, Mass.

† *Transactions*, Am. Soc. C. E., Vol. LXXXI (December, 1917), p. 645.

described in the 1920 report of the Aberthaw Company, and the order of deterioration was the same as that given by Capt. Bakenhus in his report of 1917.

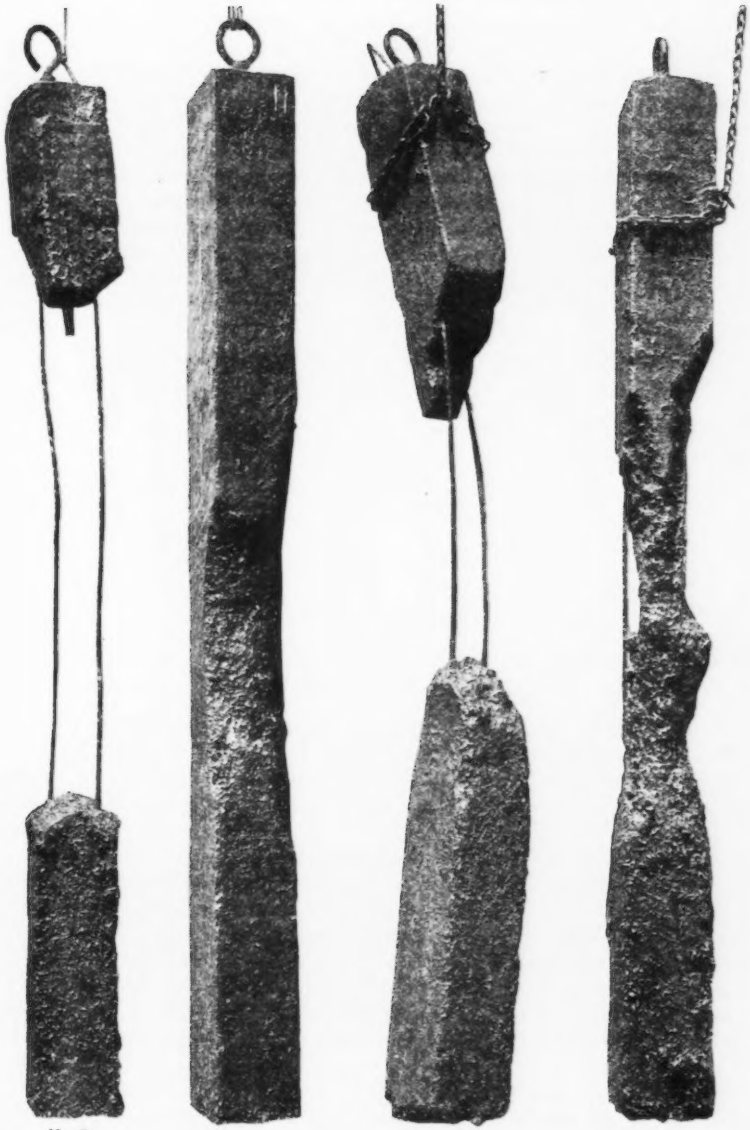
Two of the twenty-four original specimens, Nos. 19 and 21, have been lost; and five are in poor condition and may be considered to have failed. These five, which are Nos. 7, 11, 13, 22, and 23, were made of 1:3:6 concrete. Capt. Bakenhus makes nine classes, or degrees, of failure, placing No. 7 in the worst class, Nos. 22 and 23 next to the worst, that is, in Class 8, and Nos. 11 and 13 in Class 6, fair condition.

Specimen No. 7 was mixed dry, whereas the other specimens were mixed wet. Specimens Nos. 1, 4, 8, and 9 show some deterioration. Nos. 1 and 4 are of rich proportions, but mixed dry, whereas, Nos. 8 and 9 are of plastic and wet mixtures, but of lean proportion. The remainder, Nos. 2, 3, 5, 6, 10, 12, 14, 15, 16, 17, 18, 20, and 24 are in fairly good condition.

On May 24, 1922, Specimens Nos. 7, 11, 22, and 23 shown on Fig. 8, were removed for testing. No. 7 was made of three average, normal Portland cements, Vulcanite, Alpha, and Giant, in equal parts, thoroughly mixed, and then repacked in bags for use in mixing the concrete. No. 11 was made of Blanc (white Portland cement), very wet. No. 22 was made of 90% of the same cement as No. 7 and 10% of hydrated lime, very wet. No. 23 was made of cement like that of No. 7, plus Sylvester solution of soap and alum, very wet.

When the specimens were removed from the water they had, at the tops, about ¼ in. of gummy, sticky adhesion of fuel oil and dirt, which, toward the low-water mark, became thinner with a harder, somewhat glossy, surface.

No oil could be noted below the low water-line, but the specimens were coated with live mussels, which indicated that the impurities of the water were chiefly on the surface and were not sufficient to kill marine life.



Some of the specimens had previously been cracked in being removed from the water and some pieces that broke off at the cracks showed a slight brownish discoloration, which indicated that the oil had not penetrated very deeply or in any volume into the cracks. No evidence of penetration of oil below the surface of even the poorest specimens could be detected at fresh fractures of the concrete. Discoloration was not more than 3/32 in. deep. In all these specimens, the parts most damaged, namely, those near mid-tide, showed a rather disintegrated and soft concrete.

The specimens were cut to approximately square faces, the length of the test pieces being more than twice the width of the cross-section. The steel reinforcement was cut off and burned below the surface. The test pieces were then faced to a flat surface resembling terrazzo.

The top end of Specimen No. 7 was so short and so badly cracked that it was impossible to obtain a test piece larger than about 8 by 8 in. by 15½ in. All the others were of the full cross-section and about 3 ft. long.

Through the courtesy of H. W. Hayward, M. Am. Soc. C. E., they were tested at the Massachusetts Institute of Technology on June 7, 1922.

A piece of blotting paper was placed on top of the first specimen and under both ends of the remaining specimens. From the impression made on

No. 7. No. 11. No. 22. No. 23.

FIG. 8.—TEST SPECIMENS.

these sheets, it was possible to obtain the net bearing area and the character of the bearing. The edges of the test pieces were irregular and, on some, the corners were broken so that it would have been difficult to obtain the bearing area by direct measurement. In Table 8 is given the average bearing area of each end, which area is approximate only, and the writer is convinced that it is too large, rather than too small. The specimens were tested only to the point of failure. Cracks appeared longitudinally, and formed roughly two prisms the shape of an hour-glass. Reinforcing steel that was exposed after the tests, appeared to be bright. Specimen No. 7, the most porous one, was so broken after the test, that the reinforcing bar was removed. With the exception of three spots about ¼ in. in diameter which showed rust, the bar was entirely bright. This bar was from the lower end of the specimen which had been immersed for 13¼ years.

	Bottom.	224	222.5

For chemical analysis, a sample was taken from the top of the specimens, one from the lower corner of the bottom specimen and one from near the center. Mr. Herbert L. Sherman, a cement chemist, co-operated with the writer in making chemical and physical analyses of the cement used in the specimens.

After a careful and complete analysis of three samples each from Specimens Nos. 7 and 23, and a thorough study of the results, Mr. Sherman reports that it is impossible to draw any conclusions.

The result of the crushing test is given in Table 9. The original cross-section is copied from the earlier report, and is not a scaling of the specimens at the present time. It will be noted that the normal mixture of concrete shows results as good as could be expected of any concrete of this mixture and age. It will be noted also that the lower end of each of the four specimens was stronger than the upper end.

Omitting Specimen No. 7, from which only a small sample could be tested and which, therefore, may not be directly comparable with its own bottom, the other three show the strength of the top to be about 92% of that of the bottom. This indicates that there is a common law as to the condition of the concrete when permanently wet as compared with dry.

TABLE 9.—CRUSHING LOAD ON SEA-WATER TEST SPECIMEN.

No. of piece.	Original cross-section, in inches.	Area, in square feet.	Length of test specimen, in inches.	Actual section, in inches.	Total load, in pounds.	Load, in square inches, actual section.	Ratio of strength, top to bottom.
7 Top.....	15⅞ by 16 3/16	1.82	15½	57.3	157 300	2 750	0.82
7 Bottom....	15⅞ by 16 3/16	1.82	35½	231	778 800	3 375	
11 Top.....	16 by 16¾	1.86	36	236	750 200	3 180	0.93
11 Bottom....	16 by 16¾	1.86	37	240	823 900	3 435	
22 Top.....	15⅞ by 16¾	1.80	30¾	207.5	463 100	2 235	0.92
22 Bottom....	15⅞ by 16¾	1.80	36	212.5	562 100	2 645

The following summary of tests on 1:3:6 concrete mixed dry, plastic, and wet, on four brands of cement, cured in air for 1.6 to 1.75 years, is given for comparison with laboratory specimens. The data on these specimens, which were 12-in. cubes, were taken from the Annual Report of the State Engineer of New York for the fiscal year ending September 30, 1897. Fifty-two specimens were crushed at the Watertown Arsenal, the dry specimens being 9% stronger than those from plastic or wet concrete:

Highest crushing strength per square inch.....2 887 lb.
Lowest " " " " " .....1 716 lb.
Average " " " " " .....2 095 lb.

In 1912, the writer built, in Portland Harbor, a fish pier that consists of a wharf, supported by concrete piers about 4 ft. square, with a heavy floor forming the wharf platform, on which a fish house was built. Most of these piers were built inside a coffer-dam, and, therefore, were cast dry and allowed to set more than a month before being subjected to the tidal action of the sea.

The two rows of piers nearest the shore, being out of water except during high tide and never being immersed more than about 3 ft., were cast between tides. An examination of these piers was made on May 25, 1922, at which time they were ten years old. All the piers cast within the coffer-dam appeared to be in first-class condition, whereas those cast between tides showed some signs of deterioration below the high-tide line.

In 1902, a series of concrete specimens was made, in order to test the protection of steel from corrosion. The concrete was of 1:3:6 proportion, with the expectation that it would be porous. The blocks were 4 in. square and 12 in. long, and had a ½-in., square twisted steel bar, 16 in. long, through the center, that projected at both ends.

At Fort Warren, the War Department immersed one series of these specimens in sea water and, after three years' testing, the remainder of this series was lost.

The second series was given to the Chief Engineer of the Metropolitan Sewerage Commission, and the specimens were immersed in a trunk sewer. After seven years, the remainder of this series was lost.

The third series of specimens was buried in ground that was always damp and at times was saturated with water. After being twenty years in the

ground a specimen from this series was removed and split open. The steel was bright in every specimen of all three series where the cement was in close contact with it; rust was present where there were voids. When the bars were originally embedded, they were coated with hard rust, but no scales. These results indicate that cement will protect steel from corrosion in unfavorable conditions.

Although there has not been time to draw final conclusions from these series of tests, and although the series is not sufficiently comprehensive to prove a general rule for all cases of immersion of concrete in sea water, it is thought that some conclusions are now justified, and ought to be helpful to those designing marine structures.

It appears, first, that the mechanical action of the elements is much more vital than the chemical action. The densest specimens show the least wear. The porous specimens which were built with the expectation that they would soon disintegrate, have done so.

Chemical action must be considered. The specimens in which the cement was low in alumina, both of lean and of rich mixtures, are in good condition. Those that had foreign ingredients (Nos. 22 and 23), of hydrated lime and Sylvester solution, show serious weakness, whereas one specimen containing 5% of clay as filler to make the concrete dense, is still in quite good condition.

The question of the quantity of water used in mixing must be considered. In a paper* by Mr. Dan Patch, photographs are shown of the specimens arranged in three horizontal rows, in the order of the quantity of water used in mixing, and superimposed is a curve showing the resistance to compression and to wear as determined by the Research Laboratory of the Lewis Institute of Chicago, Ill. The condition of the specimens shown in these photographs indicates that those containing from 9 to 10% of water are in better physical condition than the very dry or the very wet specimens.

If good workmanship is observed in the placing of concrete in forms, excess of cement and mortar is brought to the surface and produces a skin which, until abrasion has removed it, resists very well the action of sea water. The concrete is not as durable in resisting wear as this skin.

Specimens made of the poorer materials, which fail the earliest in their lower portions, due to tidal action, have proved to be durable if permanently immersed. An explanation of the reason for the upper end of the specimen showing less strength than the lower end may be due in part to the matter of suspension. In order to handle the specimens readily, $\frac{3}{4}$-in. square twisted steel bars were extended about 2 in. from the surface the full length at opposite corners. In the center of the specimen, a hole was cored into which was grouted a hook with a shank about 3 ft. long, by which the specimens were suspended. The weight of the specimen produces a tension of about 100 lb. per lin. in. in the upper 3 ft. This condition may have produced porosity, or invisible cracks, through which weathering took place. The upper end was subjected to yearly variations of temperature of probably 100° Fahr.—sometimes, to changes of many degrees within a few hours—at times to a film of ice on the surface, and to a slight degree of abrasion of floating objects in the water.

* *Engineering News-Record*, March 3, 1921.

It seems safe to conclude that if rich concrete is made from a good quality of cement, of normal composition, or low in alumina, and the material is thoroughly mixed, using 9 to 10% of water, and placed in the dry with careful spading to assure a dense surface, that durability in sea water can be assured unless the specimen is subjected to considerable abrasion, in which case it would be wise to face the concrete with a protective coating within the limits of the rise and fall of the tide. Below low tide, and above high tide, concrete as described is a practical, satisfactory, and proper building material.

DISCUSSION

HENRY S. ADAMS,* M. AM. SOC. C. E.—In his paper, the late Mr. Hodgdon described much of the new marine work that has been done around Boston Harbor, and the speaker has had a great deal to do with some of the old work that has been built there. At first, the principal kind of construction was timber cribs filled with stone. The first record that the speaker has been able to find, Boston having been settled in 1632, was that of September 10, 1673, when the town voted to "Errect a Wall or Wharfe upon the flats before the Town, from the sconce to Capt. Scarlet's Wharfe, or useing some other meanes for secureing ye said Town from Fire Ships in case of the approach of an enemie." This wall or wharf was described as being about 2 200 ft. in length, 22 ft. in breadth at the bottom, to be raised from 14 to 15 ft. in height, and to be 20 ft. broad on top for guns, and to be constructed of wood and stone. This barricade, or out wharf, as it was called, was built, and, in 1872, Atlantic Avenue was constructed over it. There is an old affidavit to the effect that it was built as a crib.

In 1710, Long Wharf was built. It is described in some of the old books as one of the longest wharves in the world, its length being more than ½ mile, reaching from Chatham Row to low water. It was built in the form of a crib. The speaker has had occasion to pull up parts of that wharf, and the timber is as sound at present, apparently, as the day it went in. It was built of white pine.

"T" Wharf, which was an excrescence on the side of Long Wharf, was built in 1715. Part of that wharf was removed for placing the foundations for the Quincy Market Cold Storage, and the timber was found to be sound, in fact, there was some difficulty in removing it.

Long Wharf, in Portland, Me., was built in 1797 of crib work. When this wharf was removed in order to build another structure, a large proportion of the logs were found to be of white pine, and trouble was encountered because the timber floated. Logs from 20 to 24 in. in diameter were dug up, that were about 20 ft. below low water. The use of piles in the building of wharves began about eighty years ago. The speaker has had occasion to pull down some of those wharves, and evidences of teredo action have been found. The teredo is active in Boston Harbor as far as Lewis Wharf. Some of the timbers were full of them. The teredo and the allied limnoria are found as far as Constitution Wharf and the piles are badly eaten. Crib wharf construction has largely ceased since pile construction began, that is, south of Maine.

FREDERIC H. FAY,† M. Am. Soc. C. E.—Of the many harbors along the coast of Maine, the one of prime importance is that at Portland, where not only the chief seaport of Maine has been developed, but also an important winter port for Canada.

Portland Harbor.—Portland, located at the southwesterly end of Casco Bay, has one of the finest natural harbors in the world. It is almost on the

* Cons. Engr., Boston, Mass.

† Cons. Engr. (Fay, Spofford and Thorndike), Boston, Mass.

open sea, but still is well sheltered; it has ample space for anchorage basins and a natural deep-water channel from the open sea almost to the shore line of its water-front.

The principal piers are within 3½ miles of the open ocean and the approach channel is so broad and straight that steamships calling regularly at this port frequently dispense with pilots and enter or leave the harbor at any time under the direction of their own officers.

Along the water-front of the city opposite that part devoted to overseas commerce is a dredged channel, 35 ft. deep at mean low water, and 30 ft. deep for the remaining distance up Fore River. The character of the harbor bottom is such that this water-front channel may readily be deepened whenever conditions warrant. The dredged parts of the harbor require little maintenance, because of the almost entire absence of sediment in its waters. The mean tidal range at Portland is 8.9 ft. and there are no troublesome tidal currents.

Although Portland is the most northerly of the principal Atlantic ports of the United States, as well as the port nearest Europe, its harbor is notably free from ice and its water-borne commerce is not interrupted throughout the severest winter.

The strategic importance of this port has been recognized by the Federal Government and Portland has been made one of the most strongly fortified harbors in the United States.

Railroads Entering Portland.—Portland is served by three steam railroads: The Boston and Maine, which operates three lines into the city; the Maine Central with its three main lines; and the Grand Trunk Railway of Canada.

The Boston and Maine Railroad connects Portland with the important manufacturing centers of New Hampshire, Vermont, and Northern Massachusetts.

The Maine Central Railroad, by its own lines or by its connection with the Bangor and Aroostook Railroad, covers practically the whole State of Maine. The Maine Central's line through the White Mountains makes connections with the Boston and Maine, Canadian Pacific, and Quebec Central. Through its connection with the Canadian Pacific Railway, the Maine Central furnishes a route to Montreal, Que., Canada, Detroit, Mich., Chicago, Ill., the Great Lakes, and the greater part of Canada, especially the Canadian West.

The principal Atlantic terminus of the Grand Trunk Railway of Canada is at Portland and this port alone is used for its winter shipping for overseas traffic. The Grand Trunk affords a direct route to Montreal, Buffalo, N. Y., Detroit, Toledo, Ohio, Chicago, and the Great Lakes, and connects with the Grand Trunk Pacific Railway crossing the Canadian West. Grain is the principal commodity exported over the Grand Trunk docks at Portland, nearly 43 000 000 bushels having been handled in the season of 1915-16. This is equal to the total grain shipments from the Port of New York for 1921.

During the winter of 1921-22, 17 000 000 bushels of grain were shipped through the Portland Terminal of the Grand Trunk, and 99 trans-Atlantic and 37 coastwise vessels have berthed at its piers.

Portland the Natural Winter Port for Canada.—Portland is pre-eminently the natural winter port for the Dominion of Canada. It is only 297 miles from Montreal, and its connection with that city, *via* the Grand Trunk affords a rail route of relatively easy grades, particularly favorable for the movement of east-bound freight. The Canadian winter ports of St. John and Halifax, on the other hand, are, respectively, 481 and 842 miles from Montreal, *via* routes of steeper grade over which freight movement, especially in winter, is much more difficult and expensive. Had Maine been Canadian territory, Portland would no doubt be the leading port of Canada, or, at least, equal in importance to Montreal.

Portland's Belt Line Railroad.—Portland possesses one asset of great importance to the development of any port, namely, a belt line railroad which reaches every part of its water-front. This belt line is made up of trackage of the Portland Terminal Company (which is owned jointly by the Boston and Maine and the Maine Central Railroads and handles the traffic of both these roads in and near Portland) and of trackage owned by the Grand Trunk Railway. Along the important Commercial Street water-front of the city, each company has running rights over the tracks of the other, so that any wharf in this district is accessible on equal terms to all railroads entering the city.

Portland's Water-Front Developments.—Portland is well supplied with coal-handling and fuel-oil plants, most of which are up to date in capacity, equipment, and depth of water at adjoining berths. It also has suitable wharves for handling pulp wood, sulphur, and china clay used in the paper industry, not only of Maine, but of other parts of the country.

The remaining wharves along the water-front, with the exception of the Grand Trunk Terminal, are old and more or less obsolete, having been built in the days of sailing ships, when Portland had an extensive trade with the West Indies. These wharves are now used either for coastwise shipping, or by business and manufacturing concerns, many of which could be accommodated with equal facility away from the water-front.

Grand Trunk Railway Terminal at Portland.—Until the present time, the only overseas terminal at Portland has been that of the Grand Trunk Railway System, comprising New, Ocean, Atlantic, and Galt Wharves, with two grain elevators with a combined capacity of 2 500 000 bushels and the supporting railroad yard. The first three of these wharves have transfer sheds and are used for overseas business. Although not of the latest type of pier construction, these wharves with their sheds are maintained in good condition and during the five winter months when navigation of the St. Lawrence River is blocked by ice, they accommodate a large volume of business with reasonable efficiency and dispatch. Until recently, harbor-line restrictions limited the length of these wharves to about 500 ft., a length inadequate for the larger vessels now using this terminal. In 1920, the War Department established a new harbor line about 500 ft. out from the old one, making possible the

extension of these piers so that in the future they may have a total length of 1 000 ft.

Portland's Need of Further Water-Front Development.—Within the last few years, the need of increased water-front terminal facilities has been keenly felt at Portland. Certain steamship lines have sought to establish themselves at this port, but have been unable to do so because of the lack of facilities for the accommodation of their ships. Others already established have found it difficult at times to secure suitable berthing space. The Canadian Pacific Railroad is understood to have recently sought entrance to Portland over the Maine Central Railroad and if suitable water-front terminal facilities were available, some Canadian Pacific business would probably pass through this port. The Maine Central Railroad, however, like most other roads, has not been in condition financially to embark on further water-front improvements.

Public Development of the Portland Water-Front.—Recently, however, through the instigation of the Portland Chamber of Commerce, the need of further port development at Portland has been forcefully impressed on the people of that city and of the State at large. It is now recognized that port development should not be left entirely to railroads or other private interests, as has been the case at Portland heretofore, but should be, at least in part, under public control, not only to insure development on the broadest possible lines to the greatest benefit to the State and the city, but because, in addition to the direct benefits accruing to rail and water carriers, the community at large derives a substantial indirect benefit from such developments. In the City of Portland, several millions of dollars are spent annually by rail and water carriers in the purchase of coal, provisions, and other supplies from local dealers and for the wages of longshoremen, freight handlers, and others. It is recognized that for every ton of local freight shipped to and from the city there are many tons shipped to and from the district immediately tributary to the port, as well as the inland territory of the country. The people of Maine believe that with further development of the Port of Portland, making possible an increase in coastwise as well as overseas business, the industrial and agricultural development of the entire State will be stimulated, especially as the State has available much undeveloped water power which, in these days of high priced coal, may now be economically utilized to provide cheap fuel for industrial uses.

Through legislation passed in 1919, the State and the Cities of Portland and South Portland have jointly embarked on a policy of further development of the Port of Portland at public expense. The two cities have provided the site of the first of a series of publicly owned piers and the State is constructing such a pier alongside the Grand Trunk Terminals.

New State Pier at Portland.—The site for the new State Pier, which has been purchased and deeded to the State by the Cities of Portland and South Portland acting jointly through the State Pier Site District recently established by legislative enactment, consists of Franklin Wharf, formerly owned by the Eastern Steamship Lines, Incorporated, and the berthing place of that company's coastwise lines, and of Galt Wharf, which was formerly owned by

the Grand Trunk Railway. The State is now constructing on this site a modern pier 1 000 ft. long, to be equipped with adequate sheds and modern freight-handling equipment. For the present, the pier is designed to be used both for overseas and for certain coastwise business, and it will be adequate to accommodate the largest ships that will come to Portland for many years. The new pier will project nearly 500 ft. beyond the existing piers of the adjacent Grand Trunk Terminal and will extend to the newly established pier-head line previously mentioned.

In order to provide a slip of suitable width and depth between the Atlantic Wharf of the Grand Trunk Railway and the new State Pier, Galt Wharf, which was partly an old pile structure and partly a solid fill, has been completely removed, thus providing a slip 250 ft. wide with a depth of 35 ft. alongside the new State Pier. Ultimately, this slip may be deepened to 40 ft. if desired.

In the initial development of the State Pier, the existing Franklin Wharf is being utilized in conjunction with the new work, and the new pier is being built for a width less than that proposed for its ultimate development. This will afford a berthing space of 1 000 ft. along the easterly side of the pier, which will be used for overseas and Pacific Coast traffic. The westerly side of Franklin Wharf, as at present, will continue to be used by the Eastern Steamship Lines, Incorporated, for coastwise traffic, and that company is about to re-establish a freight line to New York City, which will be berthed at the westerly side of the new pier at the outer end of Franklin Wharf. Later, when conditions warrant, it is proposed to rebuild Franklin Wharf and to widen the State Pier so as to provide a complete new structure 1 000 ft. long, 320 ft. wide, with a least depth of 35 ft. of water on all sides.

The new pier will consist of creosoted Southern pine piles supporting a deck of reinforced concrete at the inner end and a timber deck elsewhere. The pier will have two transit sheds on its easterly side. The shed at the inner end is to be 90 ft. wide by two stories high and is designed primarily for trans-Atlantic shipping with accommodations for freight on the lower or main deck and quarters for saloon passengers and immigrants on the second floor. The shed at the outer end will be 60 ft. wide and one story high and designed for freight service only. On the westerly side of the new pier, a shed 60 ft. wide is now being erected for the New York freight service. At the easterly side, the cap-sill will be 27 ft. wide between the sheds and the fender cap, with a railroad track providing for the operation of a locomotive crane and with provision also for the installation later of semi-portal gantry cranes. Railroad tracks and trucking driveways are provided also in the middle of the pier.

Grain will be brought to the State Pier from the elevators of the Grand Trunk Railway Company by an extension to the grain conveyor system of that company through a modern fireproof gallery to be constructed by the State along the easterly side of the pier, the gallery being of sufficient size for the installation of a second belt in case it should be found desirable to provide for the handling of grain from other railroads than the Grand Trunk. A working agreement has already been made between the State and the Grand

Trunk Railway by which grain will be delivered to ships at the State Pier on the same terms and conditions that it is delivered to ships at the Grand Trunk piers.

Portland Port Authority.—The administration of this new publicly owned terminal is in the hands of a State Board, known as the Directors of the Port of Portland. The Board, created by legislation passed in 1919, is composed of five members, one of whom represents the City of Portland and was appointed by the Mayor of that City, and the others represent the four Congressional Districts of the State and were appointed by the Governor. This Board is the administrative agency of the port and on it is conferred the power to acquire property by eminent domain, to make all necessary plans for the comprehensive development of the port, to take charge of and construct piers and other public works on State property, to operate such piers and administer all public works under their control, and to keep thoroughly informed as to the present and probable future needs of the port.

WILDURR WILLING,* ESQ.—Federal river and harbor works in the New England States from the Canadian border to Chatham, Mass., on the southeast point of Cape Cod, are in charge of the District Engineer of the Boston, Mass., District, a recent consolidation of the former Portland, Me., and Boston, Mass., Districts.

The following are the principal works included in the District: St. Croix River, Bar Harbor, Penobscot River, Rockland Harbor, Georges River (Thomaston Harbor), Portland Harbor, and Saco River, Maine; Newburyport Harbor, Merrimack River, Harbor of Refuge at Sandy Bay, Cape Ann, Boston Harbor, Gloucester Harbor, Beverly Harbor, Salem Harbor, Lynn Harbor, Mystic River, Malden River, Dorchester Bay and Neponset River, Weymouth Fore River, Weymouth Back River, Plymouth Harbor, and Provincetown Harbor, Massachusetts.

The principal work has been the deepening of channels and anchorage basins by dredging and removal of ledge rock; the creation of artificial harbors by the construction of breakwaters; the deepening of bars at the mouths of certain rivers by jetties; and the preservation of shore lines.

Shore protection works on the part of the United States Government date back to 1824, and with peculiar historical fitness were first undertaken at Plymouth, Mass., for the protection of Long Beach.

Long Beach.—The existence of Plymouth Harbor depends entirely on the protection and preservation of Long Beach, which is a narrow strip of land that extends 2¾ miles out from the mainland in a northwesterly direction, nearly parallel to the shore of the Town of Plymouth and distant from it about 1 mile. It affords to the harbor its only shelter from easterly storms. For the protection and preservation of this beach, various works have been built from time to time, until, finally, they have proved efficient and successful.

The works originally undertaken for the maintenance of Long Beach were light temporary structures, of various designs, which may be described as follows: The bulkheads consisted of triangular frame or of cribwork of tim-

* Lt.-Col., Corps of Engrs., U. S. A.; Dist. Engr., Boston, Mass.

ber placed at intervals of 4 ft., covered with 2-in. plank, set in a trench 12 ft. wide and 3 ft. deep, the trench and frame being filled to the level of the ground.

The jetties consisted of a framework filled with brush and ballasted with stone. The groynes consisted of small stones intermixed with brush, and sometimes brush alone. They were built perpendicularly from the main bulkhead on the seaward side, spaced 50 to 150 ft. apart, and varied in length from 75 to 265 ft., aggregating 5 250 ft. Others have been built inside the bulkhead in places where most necessary. They were made by placing brush on the surface of the beach and piling beach boulders on it to a height of about 2 ft. for a width of 5 ft. The brush groynes were made by digging a trench 2 ft. wide by 2 ft. deep, and placing brush in it upright and as close as practicable. The brush is held in place by sand well rammed into the trench, and sometimes further protected by small boulders placed in a row along the sides of the groyne. The brush rises 2 or 3 ft. above the surface of the beach.

On account of the light design of these structures, repairs had to be made from time to time until finally rubble stone dikes were built, and they have fully served their purpose and continue in good order to the present time.

Boston Harbor.—The first sea-wall was started in 1825, to preserve Georges Island, an important site for one of the defenses of Boston Harbor. Sea-walls have been constructed at Deer Island, Castle Island, Rainsford Island, Lovells Island, Great Brewster Island, Long Island, Gallops Island, and Point Allerton. All these walls have been built by the Federal Government under the direction of the Corps of Engineers. From surveys made in 1820 and 1840, respectively, it appeared that 5.7 acres had been washed away from Great Brewster Island in the interval. This is about one-fourth of the whole island, at the latter period. The 1840 survey disclosed that the preservation of the islands from the wash of the sea was indispensable, as covers of the anchorages and roadsteads, and also to the maintenance of requisite depths in the channels. The aggregate length of these walls is about 3¾ miles, and the total amount expended in their construction and maintenance is about $1 500 000.

In his paper, the late Mr. Hodgdon gave an excellent description of the three main ship channels leading into Boston Harbor. The total of all Federal expenditures to June 30, 1921, on these and the various subsidiary channels of Boston Harbor, including Chelsea Creek, Fort Point Channel, and the Mystic and Malden Rivers, Dorchester Bay and Neponset River, and Weymouth Fore and Back Rivers, has been $12 734 167 for new work, and $948 584 for maintenance. The total commerce in 1921 was 9 752 841 tons. On a capitalization of 4% and an estimate of $40 000 per year for maintenance, there results a charge to the United States of 5.6 cents per ton.

Portland Harbor.—The second harbor in importance on the New England Coast is that of Portland, Me. The existing project for Portland Harbor provides for a commodious anchorage off the eastern end of the city, with a minimum depth of 30 ft.; for the dredging of the greater part of the inner harbor to a depth of 30 ft., except for the lower part of the main harbor and its channel of approach, where the depth is to be 35 ft.; for a channel 30 ft.

deep and 300 ft. wide in Fore River up to the upper Boston and Maine Railroad Bridge; for a channel 30 ft. deep and 300 ft. wide from the anchorage to the Grand Trunk Bridge at the mouth of Back Cove; for rock excavation to give a depth of 14 ft. between the Grand Trunk and Tukeys Bridges, and a channel 12 ft. deep and 300 ft. wide thence to the head of Back Cove; for the removal of two obstructing ledges in the main ship channel to a depth of 40 ft.; and for a stone breakwater about 1 900 ft. long on the southerly side of the mouth of the inner harbor. The project depths refer to mean low water. The mean tidal range is 8.9 ft. and the extreme, 10.2 ft., although variations as great as 16 ft. have been observed under storm conditions.

The existing project executed by dipper and clam-shell dredges in material similar to that in Boston Harbor has been completed, except for the removal of ledges in the main ship channel, estimated to cost $100 000. The expenditures to June 30, 1921, have been $2 271 386, and the annual maintenance is estimated at $3 000. The total commerce in 1921 was 2 369 881 tons. This results in a cost of 4 cents per ton.

Important breakwaters have been constructed at Rockland, Portland, and Bar Harbor, Me., and at Gloucester, Mass.

Rockland Breakwater.—The Rockland Breakwater extends from Jameson Point 4 350 ft. in a southerly direction. It consists of a mound of rubble with side slopes of 1:1 to a grade of 10 ft. above mean low water, at which grade the breakwater is 20 ft. wide. On this mound is a capping course of heavy split stone granite 15 ft. wide, bringing the top of the breakwater to a grade of 14 ft. above mean low water. The total cost of the breakwater was $615 000, and the annual maintenance is about $500.

The breakwater was completed in 1904, and stood undamaged until the winter of 1920-21, when some of the rubble mound on the seaward side slipped downward, the repairs for which are estimated to be about $9 000.

Bar Harbor Breakwater.—There is also a breakwater at Bar Harbor, extending from Porcupine Island to Dry Ledge and thence in a straight line to within 600 ft. of Mt. Desert Island, to protect the harbor from southerly storms. The breakwater was under construction when the World War broke out and the work was suspended on account of high prices and scarcity of labor. It has been estimated that about 15 000 tons will be required to bring it up to the grade of mean high water, and bids have been asked recently for the completion of the job.

Gloucester Breakwater.—The Gloucester Breakwater extends from Eastern Point over Dog Bar, 2 250 ft. in a northwest direction. It consists of a mound of rubble 31 ft. wide at mean low water, surmounted by a superstructure extending 17 ft. above the grade of mean low water, formed by two dry walls of heavy split stone, inclosing a core of rubble, capped by heavy stones forming a top course 10 ft. wide, the slopes of the rubble structure being, on the harbor side, 1:1.3, on the seaward side 1:3 to a grade of 12 ft. below mean low water, and 1:1.5 thence to the bottom. On the seaward side, the breakwater has an apron of heavy rubble rising to approximately 6 ft. above mean low water, the object being to protect the lower course of stone in the super-

structure. The total cost was $410 097 and the annual maintenance is about $1 000.

The Sandy Bay Breakwater project has been recommended to Congress for abandonment. Only recently the remaining small balance in the hands of the District Engineer was diverted by authority of Congress to emergency use on the 1922 floods of the Mississippi River.

R. S. PATTON,* M. AM. SOC. C. E. (by letter).—The problem involved in the design and location of engineering works intended to protect the shore from erosion by the sea is, in many cases, a peculiarly perplexing one. That problem involves, on the one hand, attack by a combination of forces each of which varies greatly from time to time both in its strength and in its direction; and, on the other hand, a resistance to attack determined by local factors of which the configuration of the shores, the character of the material composing them, and their accessibility to attack are merely typical.

This means that the engineer undertaking the erection of protective works must consider each locality as a unit. No adequate general rules can be laid down for his guidance. For example, studies of conditions along the New Jersey Coast indicate (the studies have not progressed sufficiently to justify a final conclusion) that each of the many inlets along that coast presents its own problem, and that protective works which would accomplish their purpose at one inlet might fall short of such accomplishment at the adjacent inlet, 10 miles distant. The writer does not mean to imply that there is any radical variation, in that short distance, in the nature of the attack from seaward. It seems more probable that the varying results noted are due to modifications of the seaward attack by the body of inland water.

It follows, therefore, that the confidence with which the engineer can undertake the construction of protective works will be in direct ratio to the thoroughness with which it has been practicable for him to determine the nature of the change which he undertakes to check, and the character of the forces producing it. Unfortunately, neither of these factors can be readily determined. In the United States, data on the subject of shore protection are meager, and such data as exist are not in a form readily accessible to the engineer. Consequently, many forms of protective works have been erected, which have failed to meet expectations, largely because local or private interests have not been in a position to undertake the extensive research necessary to ascertain the facts which, under more favorable conditions, would have formed the basis for the design of their structures.

The Federal Government has collected much data bearing on this subject. In practically all cases, this material has been gathered to serve some specific purpose other than shore protection, and its additional value in connection with studies of this character has been overlooked or ignored. It is fragmentary; one Bureau has collected a certain set of facts, a second Bureau another set. Each, by itself, may be of little value for this purpose; combined, they may be of great value. It is to be hoped that some day this material will be placed in shape for the use of the engineer. Meanwhile, however, the engi-

* Hydrographic and Geodetic Engr., U. S. Coast and Geodetic Survey, Washington, D. C.

neer derives little benefit from it because, in most cases, he either does not know of its existence, or he does not know how to secure it.

It is not practicable for the engineer to obtain and utilize all this information. After eliminating a large part of it, a remainder exists, in most cases, readily obtainable at slight cost, which bears so directly on his problem that he would make a great mistake if he failed to take advantage of it if the project is of magnitude. The writer will endeavor to indicate briefly the character of this latter assistance which it is possible for various agencies of the Federal Government to render.

The engineer must seek answers to two questions: (1) What is the nature of the change taking place; and (2), what forces are causing it?

Much progress toward the answer to the first question can usually be made by studying the topographic and hydrographic surveys made by the Federal Government. For the past hundred years, the Coast and Geodetic Survey has been making such surveys along the Atlantic Coast, and the frequency of re-surveys usually depends on the rapidity with which changes are occurring. For example, the New Jersey Coast is covered by three series of topographic surveys and an additional one by aerial photography, with from six to ten surveys of the various inlets. The Army Engineers, also, have made many surveys at localities where improvements have been proposed.

The surveys by these two organizations furnish a picture of successive stages in the development of the present shore, sufficiently separated to eliminate effects due to transitory causes, and thus enable one to deduce with considerable accuracy the general character of the evolution in progress.

The next step is to discover what forces operate and how they operate, to cause the changes observed. This is a much more difficult question than the preceding one, and the engineer can nowhere find the answer as he did in the first case. The best he can do is to secure data from all possible sources and then rely on his own judgment for the proper correlation of such data with the changes observed.

A great deal of valuable information can be obtained from persons having local knowledge, but information of this kind must be used with caution. It is usually fragmentary and superficial. Temporary effects and apparent causes are mistaken for basic factors. Therefore, the assurance with which such material can be utilized will be increased if the engineer can secure a background of fact against which to measure it. The material which the Federal Service can furnish, is valuable as supplying this background.

The Weather Bureau has detailed statistics from which may be determined wind effects, the direction, frequency, duration, and velocity of prevailing winds and storm winds, respectively.

The Coast and Geodetic Survey can furnish detailed information regarding the tides and currents at many points along the coast.

The Bureau of Lighthouses and the Coast Guard have made studies of this subject in connection with the need for protection of their stations, which contain information of value. In addition, the employees of those Services stationed at various points along the coast will be found to be particularly

well informed regarding weather, currents, and waves, and their effect on the shore line in their immediate vicinity.

There is still another important element in the assistance which the Federal Government can render. There are engineers in these various units of the Federal Service, whose normal work is closely related to this problem. The knowledge and experience they have thus acquired, if applied to studies of the kind here suggested, would aid materially in their solution.

The writer does not pretend to speak with authority for all Services. His experience has been, however, that they are uniformly zealous to serve the public in every possible way, and that they would gladly assist in this matter to the limit of their facilities. For example, to mention a single specific instance, the State of New Jersey, aroused by the alarming encroachment of the sea on its beaches, has instructed its Board of Commerce and Navigation to study the problem and undertake protective measures. That Board has organized an Advisory Board of Engineers to co-operate with it, which Board includes representatives of two Federal Services, the Army Engineers and the Coast and Geodetic Survey.

What the Government is doing for New Jersey, it will be equally willing to do for other States.

A. H. Rhett,* Assoc. M. Am. Soc. C. E. (by letter).—The fact is now established that concrete in contact with sea water undergoes disintegration under certain conditions, and the test conducted by the Aberthaw Construction Company, a final report on which has been made by Mr. Wason, has done much to establish this fact. Opinions seem to differ as to the cause of this disintegration, but the writer believes that the results of the various tests and examinations indicate the cause quite definitely.

It has been stated† that:

"Hydraulic cement is readily decomposed if intimately exposed to the chemical action of various sulphate and chloride solutions as contained in saline and alkaline waters, if the solutions are of sufficient strength, * * *. The cause of this disintegration is not certain, though it is almost universally believed that it is the reaction of the sulphate of magnesium of the sea water with the lime of the cement (formed during setting)."

It is also stated in that paper that: "The most soluble element of the cement is lime," and that the action is more vigorous in set cements than in unset cements, because "in set cements a considerable part of the lime has been already hydrated." And, further, that "contrary to the opinion of the many, there is no apparent relation between the chemical composition of a cement and the rapidity with which it re-acts with sea water."

The Aberthaw test confirms the statements just mentioned in demonstrating that the specimen to which hydrated lime had been added, showed very active disintegration. These findings have been confirmed by other investigators and seem to establish the fact that the disintegration of concrete by sea water is caused by the reaction of the sulphate and chloride solutions

* Gen. Sales Mgr. and Engr., Toch Brothers, New York City.

† "Action of the Salts in Alkali Water and Sea Water on Cements," U. S. Bureau of Standards, *Technologic Paper No. 12.*

of the water with the free lime (formed during setting) present in the concrete. Investigation has further disclosed that disintegration occurs principally where the concrete is alternately wet and dry, as between the high and low-water marks. In some cases, however, even under these conditions, disintegration does not occur. The question, therefore, is: If concrete contains lime, which is disastrously affected by ingredients in sea water, why does disintegration occur chiefly where the concrete is alternately wet and dry, and, even then, does not always occur? The answer can be summed up in one word—porosity.

It would seem that sea water is not sufficiently strong in the sulphate and chloride solutions to start this chemical action. If, however, the concrete is porous, each flushing fills the pores, and each drying out leaves a minute deposit of the salts. This process, repeated indefinitely, eventually produces a sufficiently concentrated solution in the pores to produce the chemical reaction and accompanying crystallization which disrupts the concrete. This action has been found to penetrate deep into the concrete—as much as 4 or 5 ft. It should be clear, then, that if concrete can be made non-porous, it will not be subject to this action of concentrated solutions and, therefore, will be stable in sea water.

L. F. BELLINGER,* M. AM. SOC. C. E. (by letter).—The U. S. Bureau of Standards has investigated the action of sea water on concrete structures, and the report of Messrs. Wig and Ferguson on this subject has been published by the Bureau of Yards and Docks of the Navy Department,† in which reference is made to the various concrete quay walls in the Brooklyn Navy Yard, that have been built at various times during the last thirty years. Pertinent extracts from the report are, as follows:

"The condition of the structures built between 1901 and 1904 is in striking contrast with those built prior to this period. * * * None of these walls has been repaired and, with one exception, the wall at berth 17-*h*, none is appreciably deteriorated."

* * * * * * * *

"Much of the repair work and replacement work which was carried on subsequent to 1912 has deteriorated to a considerable extent. In some cases, as at wall berth 1-*a*, rebuilt in 1913, the repair work is in need of extensive repairs now."

* * * * * * * *

"There are defects 'in the case of the reinforced concrete in Piers *E* and *F*, in which the cracking of the concrete is due to the corrosion of the embedded reinforcement which is uncoated and not embedded to a sufficient depth.'"

The report shows that the structures built during the period, 1901-04, are better than any built before or since, in that Navy Yard. After fifteen years, no repairs were necessary to such structures, whereas, after three years, extensive repairs were needed in a quay wall that was rebuilt in 1913. It appears desirable, therefore, to examine in detail the conditions that provided a concrete quay wall on which no repairs were needed after thirteen years, par-

† *Bulletin No. 28*, October, 1917.

ticularly as to the plasticity or workability of the concrete mixture and the workmanship required in placing it.

The materials were ordinary, high-grade aggregate and cement, secured about New York City on competitive bids. In his paper, Mr. Wason shows well the effect of too little water in concrete for use in sea water. Numerous laboratory experiments at various universities show the great deteriorating effects of too much water in concrete in any location. Both too much and too little water are dangerous, because when concrete is too dry or too wet it is more easily mixed than when it is "just right". A description of what is "just right", as determined by long experience, is the purpose of this discussion.

In their report, previously mentioned, Messrs. Wig and Ferguson describe the sea-wall concrete as being "plastic". That term is very good, but, in the West, the equivalent term is "ankle-deep concrete", and, in the East, the term, "quaking mixture", is used. Neither term is quite correct for describing physically that quality of the concrete placed in the Brooklyn Navy Yard in 1901-03. This concrete was a 1:2:4 mix that was turned three times on the mixing-board, shoveled into wheelbarrows, dumped into the forms, and rammed into place. A light ramming produced a jelly-like mass, into which the workmen's feet would sink from 1 in. to 2 in. The mortar facing was a 1:2 composition, placed by shovel next to the forms as concrete was placed directly back of it, thus securing a facing 2 in. thick integral with the concrete, but no precision was attempted on any plane of demarcation between the facing and the concrete. The degree of plasticity of the mortar was the same as that of the concrete. From the foregoing, it may be seen that less ramming was used than would have been necessary with a "quaking" mixture and, therefore, a little more water was used; also, that appreciably less water was used than in the Western "ankle-deep" concrete. Frequently, the tide rose over the soft concrete within 15 to 30 min. after it had been placed in the forms.

In 1895, the writer began the mixing of "concrete medium" with the disapproval and scorn of contractors and foremen. The explanation given then was that a certain quantity of water was necessary for the concrete properly to "set"; that less than that quantity would result in a weaker, more porous concrete; and that a slight excess of water would, by heavy ramming which was then the practice, force surplus water to the surface where it would either run off or evaporate. Although it was then considered as an unsound practice, it was insisted to be far better to have too much water than too little.

The first opportunity for mixing concrete "exactly right", occurred at the Brooklyn Navy Yard, in March, 1901. This "sticky" concrete was more difficult to handle than the dryer mixture and close inspection was necessary to secure concrete approximating closely the "exactly right" plasticity, because extra labor was required and this causes friction. Nevertheless, results were obtained that proved the great economy in repairs which is mentioned in the report of the Bureau of Standards.

The writer concurs in the conclusions of Mr. Wason regarding concrete for use in sea water. When the moisture freezes and swells, a grain of sand

or a pebble is forced out of place. Deterioration proceeds slowly in a mortar facing 2 in. thick as compared with the rate when the concrete itself is exposed to the freezing and thawing process.

The Standard Cement Specifications of the Navy Department have provided ample protection against chemical action. Abrasion from floating ice and from wave action is certain to occur. It will progress more rapidly in the concrete than in the mortar facing, because larger particles will be removed. Mortar facing from low tide to high tide should be thicker than in other parts of the wall, and some facing should extend to the top of the wall and across the coping, unless a stone coping is used.

The record of these particular quay walls and of recent laboratory tests have proved that the quantity of water used in mixing is of the greatest importance. The kind of water is of little importance; in some of the walls, fresh water was used for mixing, but in most of them East River water was used.

Failures in some seaside concrete structures and in the Boston Navy Yard samples show well what not to do. Sloppy concrete and dry concrete are thereby proved to be taboo. This discussion has been written with the desire to assist in showing what to do to secure the most durable concrete in sea water.

D. E. Hughes,* M. Am. Soc. C. E. (by letter).—Eight large series of tests of 1:3 sand briquettes were made years ago, on account of the San Pedro breakwater. All these tests were similar, except in kind of water used in mixing and in time of immersion. Series *A*, *B*, *C*, and *D* were mixed with sea water. After 24 hours, Series *A* and *B* were immersed, *A* in sea water and *B* in fresh water. Immediately on being made, Series *C* and *D* were immersed, one in sea water and the other in fresh water. Series *E*, *F*, *G*, and *H* were mixed with fresh water, *E* and *F* being immersed after 24 hours in fresh water and sea water, respectively, and *G* and *H* being placed immediately, *G* in fresh water and *H* in sea water. In all cases, the briquettes remained in their moulds 24 hours without being removed from the glass plates on which they were made.

All these briquettes developed practically equal strengths, except those of Series *H*, which, at every age and without exception, were decidedly weaker. The opinion was reached that, in Series *H*, mechanical interference with setting resulted from the sea water displacing the lighter fresh water, and this led to the advice to use sea water in the mixing of concrete that is to be exposed to sea water before setting. In large masses of mortar or concrete, the displacing of fresh water by salt water would be less complete and the weakening less pronounced.

Respecting consistency of concrete, the depth one sinks into fresh concretes, even of equal wetness, depends on whether there is much, little, or no excess of mortar, and whether the aggregate is of broken stone or the more easily displaced rounded gravel. Therefore, such expressions as "ankle-deep", etc., are hardly indicative of relative wetness, except in the case of concretes that otherwise are equal.

* Civ. Engr., San Pedro, Calif.

As to rusting of reinforcement, it can be stated that iron and steel long embedded in clay or mud under the sea have been found to be well preserved, because the first water to reach them had only a limited effect, and the clay prevented displacements by succeeding quantities to repeat the attack. Probably, the comparative freedom of reinforced concrete from cracking below low tide is similarly explained. At higher elevations, both gravity and evaporation operate to make room for fresh water to continue the rusting and swelling of steel.

In Southern California, the earliest failures are above high tide where concrete is reached only by salt air and spray and where no animal or vegetable matter or other scum attaches to seal the pores against the renewal of the waters.

The need of guarding against rock-borers may also be mentioned. In the office of J. W. Ludlow, M. Am. Soc. C. E., Harbor Engineer, Port of Los Angeles, there are specimens of concrete attacked by such borers. These specimens were obtained from concrete pile jackets placed 14 years ago and recently removed on account of channel widening at East San Pedro. These borers make small entry holes, but they immediately enlarge to 1 in. in diameter, and some of them have extended through the 3-in. jackets.

November 18, 1922.

* Presented to the Annual Meeting, January 17, 1923.

To the President and Board of Direction,

American Society of Civil Engineers:

The Special Committee on Specifications for Bridge Design and Construction has held three meetings since its report* of November 16th, 1921, was presented to the Annual Meeting of the Society on January 18th, 1922, and has completed its Specifications for Steel Railway Bridge Superstructure.

The Tentative Specifications for Steel Railway Bridges which were submitted with the report mentioned, have been fully discussed,† and the specifications presented herewith are the result of the Committee's interpretation of such discussions.

It seemed advisable that these specifications should not follow the exact lines of specifications previously offered by other technical societies, as the purpose of this Society is advisory rather than administrative. For that reason, the subject is treated in a general manner, instead of entering into explicit details which should be left to the individual engineer in the execution of work under his direction. The Committee has reviewed the subject again from its origin, has considered all suggestions offered, and, in formulating these final specifications, has endeavored to cover the fundamental principles of design, leaving to each engineer the privilege of adding such details as may particularly meet the condition of his practice or the requirements of his railroad.

Although the specifications follow what, for many years, has been considered good practice, the natural progress of more recent experience and study has also been recognized. They represent, it is believed, the most advanced practice that is justified at the present time.

It is considered desirable that a specification emanating from this Society should apply to spans of indefinite length, that such details as the number of trusses to be used, and other matters of varied opinion, should be left to individual judgment, as influenced by local or special conditions, and even in a matter such as the clearance diagram, it is suggestive rather than final.

For estimating the dead load, the weights of gravel and ballast have been classed together as 120 lb. per cu. ft., and all timber has been specified as 5 lb. per ft. B. M., as treated timber may be introduced at any time during the life of the bridge. The weight of steel rails, with fastenings, has been specified as 200 lb. per lin. ft. of track.

Perhaps the greatest advance has been made in the provision for live load. The Class M engine, proposed by D. B. Steinman, M. Am. Soc. C. E.,‡ has so many advantages for heavy loading that the way has been opened for its gradual introduction, if desired. Suggestions that similar results might be obtained by using heavy Class E engines, with relatively lighter train loads, do not conform to the present tendency toward heavier cars. The typical engines, E-10 and M-10, have been used as a basis, and moment diagrams have been inserted in the Appendix, as from these, any proportional increase may be readily produced.

---

* *Proceedings*, Am. Soc. C. E., December, 1921, Papers and Discussions, p. 683.

† For abstracts of these discussions, see p. 532.

‡ See p. 606.

Much attention has been given by the Committee to the subject of impact. Various formulas were studied and compared with the tests, but none was found to conform with equal satisfaction to the tests of chord and of web members. It was thought that the information may not yet be sufficiently complete to justify a change from the formula which has been in service many years and has produced serviceable bridges.

It has been well recognized by those who have the responsibility of the maintenance of old bridges that they should be properly proportioned for the ultimate load, as an overloaded bridge will not receive equal service by any other method; some members of the truss might be relatively weak and require the condemnation of the entire bridge. As a step toward meeting this condition, Article 106, on overload, has been inserted. There is great reluctance in adopting the overload stress of 24 000 lb. per sq. in., but it is believed that when the stress of 20 000 lb. per sq. in. is exceeded, a "slow order" will be placed on the bridge, and the structure watched for signs of deterioration. It is recognized, however, that the bridge should be proportioned for extreme contingencies.

In the matter of longitudinal force, attention is called to the error of past practice, which has been honored more in its breach than in its observance. The coefficient of friction, estimated at 20%, has been the basis of all specifications for the sudden starting or stopping of trains; but the fact that the brakes on freight cars are designed so that the wheels will not skid under an empty car, limits their efficiency to 20% of that weight, and as a loaded car may weigh four times as much as an empty one, the braking power, being 20% of the empty car, will be only 5% of the loaded car for which the bridge is designed. The specification of 10% for sliding friction of the train is, therefore, conservative.

After a study of the full-sized column tests and the derivation of various column formulas, keeping in mind the requirements of long-span bridges and the rating of existing bridges, the Committee adopted the Euler-Rankine column formula, $p = \dfrac{16\,000}{1 + \dfrac{l^2}{13\,500\,r^2}}$, for design, believing it to be the most practicable formula of scientific origin, long established in practice, and best applicable to unusual or extraneous conditions. The use of the right-line formula, $p = 16\,000 - 70\,\dfrac{l}{r}$, would be permitted under these specifications, but if this right-line formula had been specified, it would have precluded the use of the Euler-Rankine formula with its many advantages.

Although the derivation of the Euler-Rankine formula makes it applicable to columns of indefinite length, it has been thought that, for vibrating structures, the length of the column should be limited so as to insure rigidity under sudden motion. The assumed limits placed in Article 202 are for this purpose, and may be modified later, if experience or judgment so dictates.

In providing for the increased allowable stress on steel of greater strength than that of the structural grade, it is recognized that the modulus of elasticity

of the stronger steel is practically unchanged, and the Euler-Rankine formula, with a modified numerator and denominator, as specified, is equally applicable. For the stronger steel, in which the yield point may approach its ultimate strength, the proportional increase of the allowable stress may be so close to the ultimate as to encroach on a proper factor of safety. For this reason, the increase has been restricted in application to a yield point of not more than 70% of the ultimate strength.

In his discussion* of the strength of lattice-bars, Otis E. Hovey, M. Am. Soc. C. E., has assumed that the curve of flexure of the column was a parabola and determined the numerator of his formula to be $4\ P\,l$. If the curve had been assumed to be that of a sinusoid, the numerator would have been $\pi\ P\,l$. It may be assumed, therefore, that an intermediate value of $3.357\ P\,l$ may be used for the numerator and thus simplify the formula to $R = \frac{P\,l}{4\,000\,y}$. This formula has been adopted by the Committee.

The spacing of stiffeners on plate girders does not justify undue refinement, and it is believed that the simple clause adopted will meet every purpose.

The specification for workmanship has been condensed as much as seemed to be practicable to meet the requirements of first-class work. The requirement for sub-punching and reaming has been generally avoided in order to save unnecessary expense, but it has been found that even the accuracy of the multiple punch will not produce a large number of plates that may be satisfactorily assembled without reaming. When the plates exceed five in number, it is deemed advisable to sub-punch and ream.

Heretofore, the permissible difference between pin-hole and pin, 5 in. in diameter or less, has been restricted to $\frac{1}{50}$ in. This restriction has been extended to apply to pins 8 in. in diameter, or less.

The Committee presents the Specification for Steel Railway Bridge Superstructure in completed form, and recommends its adoption.

Respectfully submitted,

For the Committee,

HENRY B. SEAMAN,
Chairman,

C. R. HARDING,
Secretary.

SPECIFICATIONS FOR STEEL RAILWAY BRIDGE SUPERSTRUCTURE

SECTION A.—GENERAL

1.—These specifications cover the design of fixed span bridges of all lengths and require first-class design, material, and workmanship.

2.—Material.—Bridges shall be made wholly of structural steel, except where otherwise specified. Castings shall be of steel, unless cast iron is specifically authorized by the Engineer.

3.—Notice to Engineer.—The Contractor shall give ample notice to the Engineer of the beginning of rolling and of shop work, so that inspectors may be provided. No material shall be rolled, or work done, before the Engineer has been notified where the orders have been placed.

4.—Type of Bridge.—The type of bridge to be used for various span lengths may be as follows:

Rolled beams up to	30 ft.
Plate girders from	30 to 125 ft.
Riveted trusses from	100 ft. and more
Pin-connected trusses from	150 ft. and more

5.—Spacing of Girders and Trusses.—The girders of deck bridges and stringers, where two are used on each track to carry open floors, shall not be spaced closer than 6 ft. 6 in., center to center.

The width between centers of trusses or girders shall be sufficient to give lateral stiffness and to prevent overturning by the specified lateral forces, and, in no case, shall be less than one-twentieth of the span.

6.—Depth Ratios.—The depth of trusses preferably shall be not less than one-tenth of the span. The depth of plate girders preferably shall be not less than one-twelfth of the span. The depth of rolled beams used as girders and the depth of solid floors preferably shall be not less than one-fifteenth of the span. If less depths are used, the section must be increased so that the maximum deflection will not be greater than if these limiting ratios had not been exceeded.

7.—Clearance.—The clearance on straight track shall not be less than that shown in Fig. 1. On curves, additional provision shall be made for a car, 80 ft. long, 60 ft. between truck centers, 14 ft. high above the top of a 6-in. rail, and with allowance for super-elevation of the outer rail. Unless otherwise specified, the super-elevation of the outer rail shall be $\frac{3}{4}$ in. for each degree of curvature, with a maximum of 6 in.

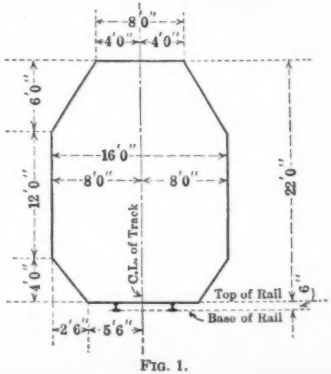

FIG. 1.

8.—Skew Bridges.—In skew bridges without ballasted floors, the end stringers or end girders for each track shall be square to the line of track.

9.—Timber Floor.—Ties shall not be less than 10 ft. long, spaced about 6 in. apart, and secured against bunching. If subjected to bending, the stress in the extreme fibers of ties shall not exceed the unit stress for timber given in Article 203, assuming a maximum wheel load, with 100% impact, to be distributed over three ties.

10.—Ballasted Floors.—Ballasted floors shall have at least 6 in. of ballast under the ties, and the ballast shall

be assumed as level with the base of rail, the weight of the ties being neglected. The live load on each tie shall be assumed as one-third of the maximum axle load distributed over a width of 10 ft.

11.—Dimensions for Calculations.—For the calculation of stresses, the length shall be:

For trusses and girders, the distance between centers of bearing;
For floor-beams, the distance between centers of trusses;
For stringers, the distance between centers of floor-beams;

and the depth shall be:

For pin-connected trusses, the distance between centers of pins;
For riveted trusses, the distance between centers of gravity of chords;
For plate girders, the distance between centers of gravity of flanges (not to exceed out to out of flange angles) unless net section modulus is used.

12.—Spans with floor systems shall preferably have end floor-beams.

Section 1.—Loads and Stresses

101.—Loads.—Stresses shall be shown separately for the following: Dead load, live load, impact, centrifugal force, and lateral and longitudinal forces. Members shall be proportioned for the combination giving maximum sections, except as otherwise provided.

102.—Dead Load.—In estimating the weight of the structure, for the purpose of computing dead load stresses therein, the following unit weights shall be used:

Steel	490	lb. per cu. ft.
Concrete	150	" " " "
Sand, gravel, and ballast	120	" " " "
Asphalt-mastic and bituminous macadam	150	" " " "
Granite	170	" " " "
Paving bricks	150	" " " "
Timber	5	" per ft. B. M.

The rails, inside guard rails, and fastenings shall be assumed to weigh 200 lb. per lin. ft. for each track.

103.—Live Loads.—The live load for each track shall consist of typical engines followed by a uniform train load, according to either Class E series, or Class M series, as may be specified by the Engineer. It shall be a multiple of one or the other of the loads with wheel spacings, as shown in Figs. 2 and 3.

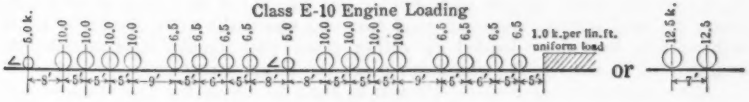

FIG. 2.

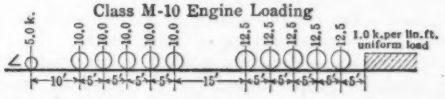

FIG. 3.

Loading E-60 or Loading M-50 is recommended for main-line bridges of American railways.

104.—Impact.—The dynamic increment of the live load shall be added to the maximum computed live load stresses and shall be determined by the formula:

$$I = S \frac{2\,000 - L}{1\,600 + 10\,L},$$

in which,

I = impact or dynamic increment to be added to live load stresses;
S = computed maximum live load stress;
L = loaded length of track, in feet, producing the maximum stress in the member. For bridges carrying more than one track, the aggregate length of all tracks producing the stresses shall be used.

Impact shall not be added to stresses produced by longitudinal and lateral or wind forces.

105.—For bridges designed exclusively for electric traction, impact shall be taken as one-third of that given by the impact formula.

106.—Allowance for Increase of Live Load.—Wherever an additional counter would be required, or reversal of stress would be caused, or heavier dimensioning would result, a member and its details shall be designed for a live load 50% greater than that given in Article 103, with an allowance of 50% increase in unit stresses.

107.—Centrifugal Force.—Structures on curves shall be designed to resist the centrifugal force of the live load applied 7 ft. above base of rail, as computed by the following formula:

$$C = \frac{0.067\ W\ V^2}{R}$$

in which,

C = horizontal centrifugal force;
W = live load, including impact;
R = radius of curve (5 730 ÷ degree of curve);
V = speed, in miles per hour = (60 — 2½ times the degree of curve).

108.—Lateral Forces.—All spans shall be designed for a lateral force on the loaded chord of 200 lb. per lin. ft. plus 10% of the specified train load on one track, and 200 lb. per lin. ft. on the unloaded chord, these forces being considered as moving.

109.—Wind Force.—Viaduct towers shall be designed for the one of the following loads that causes the greater stress:

Viaduct towers shall be designed for a force of 50 lb. per sq. ft. on one and one-half times the vertical projection of the structure unloaded; or 30 lb. per sq. ft. on the same surface plus 400 lb. per lin. ft. of structure applied 7 ft. above the rail for the assumed wind force on the train when the structure is either fully loaded or loaded on either track with empty cars assumed to weigh 1 200 lb. per lin. ft., whichever gives the larger stress.

110.—Longitudinal Force.—Provision shall be made for the starting and stopping of trains, with a coefficient of friction on the engine drivers at 20% and on the remainder of the train at 10 per cent.

111.—Temperature.—On simple spans, provision shall be made for expansion due to a variation in temperature of 120° Fahr.

112.—Alternate Stresses.—Members subject to alternate stresses of tension and compression shall be proportioned for the kind of stress requiring the larger section. If the alternate stresses occur in succession during the passage of one train, as in stiff counters, each stress shall be increased by 50% of the smaller. The connections of such members shall be proportioned in all cases for the sum of the stresses thus increased.

If the live load and dead load stresses are opposite in character, only two-thirds of the dead load stress shall be considered as effective in counteracting the live load stress. This reduction of dead load shall not be made in proportioning members subject to alternate stresses.

113.—Combined Stresses.—Members subject to both axial and bending stresses shall be proportioned so that the combined fiber stresses will not exceed the unit stresses given in Article 201. In members continuous over panel points, three-fourths of the bending stress computed as for simple beams shall be added to the axial stress.

114.—For stresses produced by combination of longitudinal or lateral and wind forces with live load, dead load, impact, and centrifugal force, the unit stresses may be increased 25% over those specified in Article 201. When secondary stresses are included, the unit stress may be increased 33⅓ per cent. In no case shall the section be less than that required for dead load, live load, impact, and centrifugal force at the unit stresses specified in Article 201, or less than that required if secondary stresses are not considered.

115.—Secondary Stresses.—Secondary stresses shall be avoided where possible in designing and detailing. In ordinary trusses without sub-paneling, secondary stresses due to distortion need not be considered in any member the width of which measured parallel with the plane of flexure is less than one-tenth of its length. All other secondary stresses shall be considered.

Section 2.—Unit Stresses

201.—The unit stresses to be used in proportioning the several parts of the structure shall be as follows:

Allowable Stresses for Structural and Rivet Steel:

	Kips per* square inch.
Tension	16.0
Compression (one diameter)	16.0

Compression on columns:

$$p = \frac{16.0}{1 + \frac{l^2}{13\,500\,r^2}}$$

in which:

p = allowable unit stress;
l = length of member, in inches;
r = least radius of gyration of member, in inches;

but not to exceed the value for $\frac{l}{r} = 40$.

Bending in extreme fibers of rolled shapes, built sections, and girders, net section	16.0
Bending in extreme fibers of pins	24.0
Shear in plate-girder and I-beam webs, net sections	12.0
Shear in pins and power-driven rivets	12.0
Shear in turned bolts and hand-driven rivets	10.0
Bearing on pins, power-driven rivets, outstanding legs of stiffener angles, and other steel parts in contact	24.0
Bearing on turned bolts and hand-driven rivets	20.0
Bearing on countersunk rivets. Only one-half the countersink shall be computed as bearing surface.	
Bearing on rollers per linear inch	0.6 d

* 1 k. = 1 000 lb.

in which,

d = diameter of roller, in inches.

For cast-steel shoes and pedestals, the allowable unit stress for structural steel will apply.

For members composed of steel of greater strength than structural grade the allowable stresses may be increased in proportion to the higher yield point of the stronger steel, provided the yield point is not more than 70% of the ultimate strength. In the column formula, the fractional part of the denominator should be increased in the same ratio.

202.—Limiting Length of Members.—The lengths of main compression members shall not exceed 100 times their least radius of gyration, and those for wind and sway-bracing 120 times their least radius of gyration.

The lengths of riveted tension members shall not exceed 200 times their least radius of gyration.

203.—Allowable Fiber Stress on Wooden Cross-Ties.—(The maximum wheel load with 100% impact, will be distributed over three ties):

	Kips per square inch.
White oak and dense yellow pine	2.0
Dense Douglas fir	1.5
White pine, ordinary yellow pine, and spruce	1.2

204.—Allowable Pressure on Masonry.—

	Kips per square inch.
Granite masonry	0.8
Limestone and sandstone (good quality)	0.4
Concrete (1:2:4)	0.6

Section 3.—Details of Design

301.—Thickness of Material.—In bridges designed for live loads of more than E-40, material less than $\frac{3}{8}$ in. in thickness shall not be used, except for fillers.

In bridges designed for live loads of E-40 and less, material $\frac{5}{16}$ in. in thickness may be used.

302.—Open Details.—Details shall be arranged so as to give free access for inspection and painting. Water-pockets shall be avoided.

303.—Compression Members.—Compression members shall be designed so that the metal shall be concentrated as far as feasible in the webs and flanges, and so that the center of gravity of the section may be as near the center line of the member as practicable.

304.—Rigid Members.—Hip verticals and members performing similar functions, and the two end panels of the bottom chords of single-track pin-connected bridges preferably shall be rigid.

305.—Net Sections.—Net sections shall be used in all cases in calculating tension members; and, in deducting rivet holes, they shall be taken as $\frac{1}{8}$ in. larger than the nominal diameter of the rivet. The weakening effect of a staggered rivet shall be allowed for by deducting from the transverse section a strip, w in width, as given by the formula:

$$w = h - \frac{s^2}{4\,g},$$

in which,

w = width, in inches, of strip to be deducted;
h = diameter of rivet hole, in inches;
s = stagger, or longitudinal spacing of rivet with respect to rivet on last gauge line, in inches;
g = distance between gauge lines, or transverse spacing, in inches.

306.—Pin-connected riveted tension members shall have a net section back of the pin-hole, parallel to the axis of the member, of not less than the required net section of the body of the member, and shall have a net section through the pin-hole at least one-third larger than the required section. Riveted tension members shall be stitch-riveted where necessary to make a compact member.

307.—Maximum Length of Rivet.—The total thickness of plates connected by rivets shall not exceed six times the nominal diameter of the rivet to be used.

308.—Pitch of Rivets.—Rivets shall be proportioned by their nominal diameter. They shall not be spaced, center to center, closer than 3 diameters nor farther apart, in the direction of the stress, than sixteen times the thickness of the thinnest plate connected, nor farther apart, at right angles to the line of stress, than thirty times that thickness, except in the cover-plates of compression members, where the spacing may be forty times the thickness of the thinnest plate. The pitch of rivets at ends of built compression members shall not be more than 4 diameters, for a distance of one and one-fourth times the width of the member.

309.—Edge Distance of Rivets.—Rivets shall not be spaced closer to sheared edges than 1¾ diameters, nor to rolled or planed edges, except in flanges of beams and channels, than 1½ diameters, nor farther from the edge than eight times the thickness of the plate.

310.—Built Chord Splices.—Built chords subjected to compression only, when faced for bearings, shall be spliced on four sides sufficient to hold the abutting members accurately in place and to transmit at least 25% of the stress through splice-plates. Generally, they shall be spliced as near to panel points as practicable. All other joints shall be fully spliced.

311.—Extra Rivets in Packing.—Filler-plates through which stress is transmitted, or splice-plates not in direct contact with the parts they connect, shall be extended for extra riveting.

312.—Latticing Compression Members.—All segments of members in compression, connected by latticing only, shall have batten-plates at each end. The thickness of such plates shall not be less than one-fortieth of the distance between the rivets connecting them to the compression member. In no case shall the length of such batten-plates be less than 1¼ times the width of the member. Where intermediate batten-plates are used, their length shall be at least three-quarters of the width of the member.

The distance between the connections of latticing shall be such that the individual members between them, composing the column shall be relatively stronger than the column as a whole.

313.—Tension members composed of shapes shall have their separate segments connected by batten-plates, or by batten-plates and lattice-bars.

314.—Lattice-Bars.—Single lattice-bars shall generally be inclined at an angle of 60° with the axis of the member, and double lattice-bars at an angle of 45°, riveted at the intersection. Single lattice-bars shall have a thickness of not less than one-fortieth, and double lattice-bars not less than one-sixtieth, of the distance between rivets connecting them to the compression member.

315.—The latticing of compression members shall be proportioned to resist shearing stress normal to the member not less than that calculated by the formula:

$$R = \frac{P\,l}{4\,000\,y}$$

in which,

R = normal shearing stress, in pounds;
P = strength of column as a compression member, expressed in pounds;
l = length of column, in inches;
y = distance from neutral axis to extreme fiber, in inches.

In a compression member with a cover-plate, the cover-plate will be assumed to take one-half the shear.

316.—The diameter of the rivets shall not exceed one-third the width of the bar.

317.—Reinforcing Pin-Holes.—Where necessary, pin-holes shall be reinforced by plates. These plates shall be connected so as to distribute the bearing pressure proportionately over the full cross-section with a minimum of eccentricity. At least one full-width plate on each segment shall extend 6 in. beyond the near edge of the batten-plate.

318.—Forked Ends.—Forked ends of compression members should be avoided. Where forked ends are used, a sufficient number of pin-plates shall be provided to give each jaw the full strength of the compression member. At least one of these plates shall extend to the far edge of the batten-plates, and the others not less than 6 in. beyond the near edge of the batten-plates.

319.—Floor-Beam Connections.—Floor-beams preferably shall be square to the girders or trusses, and shall be riveted directly to the girders or to the posts of the trusses.

320.—Lateral Bracing.—Through bridges shall be provided with post brackets at the intermediate panel points, of sufficient strength to maintain the panel in a vertical position under the specified wind pressure. When the height of the top chord is more than 26 ft. above the floor, an overhead system of sway-bracing shall be used.

321.—In either deck or through bridges, the end sway-bracing shall be proportioned to carry the entire upper lateral stress to the support, through the end posts of the truss.

Rigid lateral bracing is preferred and no connection shall have less than three rivets.

322.—Viaduct towers shall be braced both transversely and longitudinally, with a double system of rigid diagonals with riveted connections. Longitudinal and transverse struts shall be placed at caps and bases and at all intermediate panel points. All bracing connections shall be made with gusset-plates. The struts at the base of towers shall be strong enough to slide the movable shoes and provide expansion, with the structure unloaded.

323.—Plate Girders.—Plate girders shall be proportioned by assuming that the flanges are concentrated at their centers of gravity, but in no case beyond the back of the flange angles. One-eighth of the gross section of the web may be considered as flange area, provided the web is properly spliced to transmit its bending moment. For unusual sections, the net section modulus shall be used.

324.—Compression Flanges.—The gross section of compression flanges of plate girders or I-beams shall not be less than the gross section of the tension flanges, but the stress per square inch shall not exceed:

$$16.0\ K - 0.15\ \frac{l}{b},$$

in which,

l = length of unsupported flange, between lateral connections or knee-braces, in inches; and

b = width of flange, in inches.

325.—When flange plates are used, at least one plate on each flange shall extend the full length of the girder, and on through bridges, an end and corner cover-plate shall be used. Any additional flange plates shall be of such length as to allow two rows of rivets of the regular pitch to be placed at each end of the plate, beyond the theoretical point required, and there shall be a sufficient number of rivets at the ends of each plate to transmit its stress value before the theoretical point of the next outside plate is reached.

326.—Flange plates which are spliced, shall be properly covered by extra material equal in section to the material spliced. Flange angles shall have angle splices. There shall be a sufficient number of rivets on each side of the splice to transmit the stress value of the parts cut.

327.—The webs of plate girders, wherever cut, shall be fully spliced for shear and bending.

328.—Stiffeners.—Stiffener angles shall be placed at end bearings and at points of concentrated load. Such stiffeners shall not be crimped and shall have outstanding legs proportioned for bearing and extending as nearly as practicable to the edge of the flange angles.

329.—Intermediate Stiffeners.—Webs shall be stiffened by angles riveted thereto in pairs, with outstanding legs not exceeding sixteen times their thickness and not less than 2 in. plus one-thirtieth of the depth of the girder. Intermediate stiffeners shall be placed at intervals not exceeding the depth of the web, nor 6 ft.

330.—If the depth of the web between the flange angles or side-plates is less than fifty times the thickness of the web, intermediate stiffeners may be omitted.

331.—Expansion Rollers.—All bridges, 80 ft. or more in length, that bear on masonry, shall be provided with pin-bearing bolsters, and, at one end, shall have turned rollers not less than 4 in. in diameter, placed between two planed surfaces. Spans of less than 80 ft. shall be free to move at one end on planed surfaces without rollers.

332.—The nests of rollers shall be designed so as to prevent displacement.

333.—Bearings Anchored.—Trusses shall be secured against side motion on bearing plates and rollers. The bolsters shall be joined to the trusses and the bearing plates secured to the underlying supports by bolts. Anchor-bolts shall not be less than 1¼ in. in diameter, and shall extend not less than 18 in. into the masonry. Washers shall be used under the nut. Anchor-bolts subjected to tension, as in viaduct towers, shall engage 50% more masonry than is sufficient to counteract the uplift.

334.—Eye-Bar Packing.—Eye-bars shall not be packed out of line with the axis of the member more than $\frac{1}{32}$ in. to 1 ft. Members packed on pins shall be held against side movement.

335.—Camber.—The length of truss members shall be such that the camber will be equal to the deflection produced by the dead load plus the full train load, without impact.

Section 4.—Workmanship

401.—General.—All workmanship shall be equal to the best practice in modern bridge shops. The methods used and the character of the work done shall be such that the strength of the various members, as designed, shall be fully realized.

402.—Straightening.—When necessary, the material shall be straightened by methods that will avoid any excessive local internal stresses. Sharp kinks and bends may be cause for rejection.

403.—Shearing Structural Steel.—All shearing shall be done neatly and material exceeding ¾ in. in thickness, shall have ¼ in. planed from the sheared edges.

404.—Shearing Alloy Steel.—All shearing shall be done neatly and material exceeding ½ in. in thickness shall have ¼ in. planed from the sheared edges.

405.—Rivet Holes.—Material forming parts of a member composed of more than five thicknesses of metal shall be punched, or drilled, with a tool $\frac{1}{16}$ in. smaller than the nominal size of the rivets and reamed to full size after the parts are assembled. When the holes are made after the parts are assembled, they shall be drilled full size.

406.—Rivet Holes in Structural Steel.—Material forming parts of a member composed of not more than five thicknesses of structural steel may be punched $\frac{1}{16}$ in. larger than the nominal size of the rivets, whenever the thickness of the metal is equal to, or less than, the nominal size of the rivets, plus $\frac{1}{8}$ in. All metal thicker than the nominal size of the rivets, plus $\frac{1}{8}$ in., shall be drilled from the solid.

407.—Rivet Holes in Alloy Steel.—Material, $\frac{1}{2}$ in., or less, in thickness, forming parts of a member composed of not more than five thicknesses of alloy steel may be punched $\frac{1}{16}$ in. larger than the nominal size of the rivets. Material thicker than $\frac{1}{2}$ in. shall be punched, or drilled, with a tool $\frac{1}{16}$ in. smaller than the nominal size of the rivets and reamed to full size after the parts are assembled. All metal thicker than the nominal size of the rivets, less $\frac{1}{4}$ in., shall be drilled from the solid.

408.—Drifting.—Drifting to enlarge unfair holes will not be allowed.

409.—Field Rivet Holes.—All holes for field connections, except those for bracing and similar parts, shall be reamed or drilled to a metal templet, or while the members are temporarily assembled. When the reaming or drilling is done with the pieces assembled, the parts shall be match-marked and a diagram of the marks made.

410.—Dies.—Punch dies shall not be more than $\frac{3}{32}$ in. larger than the punch.

411.—Web-Plates.—Web-plates of girders which have no cover-plates, shall be flush with the backs of the top flange angles or project above them not more than $\frac{1}{8}$ in.

Web-plates of girders that have cover-plates may be $\frac{1}{2}$ in. less in width than the distance back to back of flange angles. The ends of web-plates at splices shall not be more than $\frac{1}{4}$ in. apart.

412.—Splice-Plates and Fillers.—Web splices, plates, and fillers shall fit within $\frac{1}{8}$ in. of the flange angles.

413.—Web Stiffeners.—Web stiffeners at bearings and points of concentrated loads on the flanges, shall be faced and brought to bearing against the flange angles.

414.—Lattice-Bars.—The ends of the lattice-bars with single rivets shall be neatly rounded.

415.—Floor-Beams and Stringers.—The main sections of floor-beams and stringers shall be of exact length after riveting, and the end-connection angles shall be accurately set to length, and square.

416.—Turned Bolts.—Generally, the use of bolts instead of rivets shall not be permitted. Wherever bolts are used, the holes shall be reamed parallel and the bolts turned to a driving fit, and the threads shall be entirely outside the holes. A washer not less than $\frac{1}{4}$ in. thick shall be used under the nut and the thread burred.

417.—Abutting Joints.—Abutting joints shall be fitted close. The abutting surfaces of compression joints which depend on contact bearing shall be accurately faced.

418.—Eye-Bars.—Eye-bars shall be made by a process that will produce a uniform product. Welds will not be allowed. The form of the heads may be determined by the dies at the works where the eye-bars are made, if satisfactory to the Engineer, but the manufacturers shall guarantee the bars to break in the body when tested to rupture. The thickness of the head shall not be more than $\frac{1}{8}$ in. greater than that of the bar, except by mutual agreement in special cases.

419.—Pin Clearance.—The diameters of pin-holes shall not exceed those of the pins by more than $\frac{1}{50}$ in. for pins 8 in. or less in diameter, nor more than $\frac{1}{32}$ in. for larger pins.

420.—Pins and Rollers.—Pins more than 7 in. in diameter shall be forged and annealed. Pins 9 in. or more in diameter shall have a 2-in. longitudinal hole bored through the axis. All pins shall be turned.

421.—Steel Castings.—Steel castings shall be free from large and injurious blow-holes and shall be annealed.

422.—Bed-Plates.—Expansion bed-plates shall be planed true and smooth. The finishing cut of the planer tool shall be in the direction of expansion. Cast wall-plates shall be planed on top.

423.—Screw-Threads.—Screw-threads shall be U. S. Standard. The nuts shall fit tight.

424.—Welds.—Welds will be allowed only where the unit stress is not more than one-half the ordinary specified working stress.

425.—Pilot Nuts.—Two pilot and two driving nuts shall be furnished for each size of pin.

426.—Field Rivets.—Field rivets shall be furnished in excess of the nominal number required to the amount of 10% plus 10 rivets of each size and length.

427.—Shop Painting.—All surfaces that come in contact or that are closed shall receive one coat of approved paint before being assembled. All steel shall be scraped free of scale and shall receive one coat of approved paint before leaving the shops.

428.—All machined surfaces shall receive a coat of white lead and tallow at the shop.

429.—Facilities for Inspection.—The Inspector shall be allowed access to all necessary parts of the works.

430.—Inspector's Authority.—The Inspector shall have the power to reject materials and workmanship which do not fulfill the requirements of these specifications; but, in case of dispute, the Contractor may appeal to the Engineer, whose decision shall be final.

431.—Rejection.—The acceptance of any material or finished members by the Inspector, shall not be a bar to their subsequent rejection if they are found to be defective.

Rejected material and workmanship shall be replaced promptly or made good by the Contractor.

Section 5.—Full-Size Eye-Bar Tests

501.—Material Tests.—When the acceptance of eye-bars depends on the results of full-size tests, the quality of the material, as proved by the specimen tests, shall be determined by the manufacturer.

502.—Number of Full-Size Tests.—The number and size of the bars to be tested shall be specified by the Engineer before the mill order is placed.

503.—Selection of Eye-Bars.—The test bars shall be the same section as the bars that are to be used in the structure and of the same length, if within the capacity of the testing machine. Test bars representing bars too long for the testing machine shall be selected from the full length bar material after the heads on one end have been formed, and shall then be cut and the second head formed to the greatest length that can be tested.

504.—Requirements for Full-Size Tests.—The requirement for full-size eye-bar tests shall be as follows:

	Structural steel annealed eye-bars.
Yield point, in pounds per square inch, minimum.....	30.0 k
Ultimate strength, in pounds per square inch, minimum.	55.0 k
Elongation percentage in 18 ft., minimum.....	12

The elongation shall be measured in the body of the bar including the fracture.

505.—Re-Tests.—When a bar fails to meet the requirements, two additional bars of the same size and from the same mill heat may be tested. If two of three bars tested fail, the bars of that size and mill heat shall be rejected.

506.—Payment for Eye-Bars.—Eye-bars thus tested which meet the requirements of these specifications, shall be paid for by the purchaser at the same unit price as for the structure. Bars which fail to meet the requirements of the specifications, and all bars rejected as a result of the tests, shall be at the expense of the Contractor.

Section 6.—Weighing and Shipping

601.—Weight Paid For.—The payment for pound-price contracts shall be based on the weight of metal in the fabricated structure, including field rivets shipped. The weight of erection bolts, field paint, and all boxes, crates, or other containers used for packing, together with sills, struts, and rods used for supporting members during transportation, shall be excluded.

Weights paid for shall be shop-scale weights unless otherwise provided. If specified in the contract or permitted by the Engineer, computed weights, as hereinafter provided, may be made the basis of payment.

602.—Variation in Weight.—If the weight of any member is more than 2½% less than the computed weight, it may be cause for rejection. This applies to both pound-price and lump-sum contracts.

If the total scale weight of any structure exceeds the computed weight by more than 2%, the weight in excess of 2% above the computed weight shall not be paid for.

603.—Weighing of Members.—Finished work shall be weighed in the presence of the Inspector, if practical. The Contractor shall supply satisfactory scales and shall perform all work involved in handling and weighing the various parts.

604.—Computed Weight.—The weight of steel shall be assumed at 490 lb. per cu. ft. The weight of cast iron shall be assumed at 450 lb. per cu. ft.

The weights of rolled shapes, and of plates up to and including 36 in. in width, shall be computed on the basis of their nominal weights and dimensions, as shown on the approved shop drawings, deducting for copes, cuts, and open holes.

The weights of plates wider than 36 in. shall be computed on the basis of their dimensions, as shown on the approved shop drawings, deducting for cuts and open holes. To this shall be added one-half of the allowed percentages of overrun in weight given in Article 711.

The weight of heads of shop-driven rivets shall be included in the computed weight, assuming the weights to be as follows:

Diameter of rivet, in inches:	Weight for 100 heads in pounds:
½	4.5
⅝	8.5
¾	14.5
⅞	21.5
1	31.0

The weight of castings shall be computed from the dimensions shown on the approved shop drawings, with an addition of 10% for fillets and overrun.

To the total computed weight of metal may be added an allowance of 0.4 of 1% for shop paint.

Section 7.—Structural Steel for Bridges

These specifications conform to the Standard Specifications for Structural Steel for Bridges of the American Society for Testing Materials.

701.—Steel Castings.—The Standard Specifications for Steel Castings (Serial Designation, A27), adopted by the American Society for Testing Materials, shall govern the purchase of steel castings for bridges. Unless otherwise specified, Class B castings, medium grade, shall be used.

I.—Manufacture

702.—Process.—The steel shall be made by the open-hearth process.

II.—Chemical Properties and Tests

703.—Chemical Composition.—The steel shall conform to the following requirements as to chemical composition:

		Structural steel.	Rivet steel.
Phosphorus	Acid	not over 0.06%	not over 0.04 %
	Basic	" " 0.04%	" " 0.04 %
Sulphur		" " 0.05%	" " 0.045%

704.—Ladle Analyses.—An analysis of each melt of steel shall be made by the manufacturer to determine the percentages of carbon, manganese, phosphorus, and sulphur. This analysis shall be made from a test ingot taken during the pouring of the melt. The chemical composition thus determined shall be reported to the purchaser or his representative, and shall conform to the requirements specified in Article 703.

705.—Check Analyses.—Analyses may be made by the purchaser from finished material representing each melt. The phosphorus and sulphur content thus determined shall not exceed that specified in Article 703 by more than 25 per cent.

III.—Physical Properties and Tests

706.—Tension Tests.—

(*a*).—The material shall conform to the requirements as to tensile properties given in Table 1.

TABLE 1.

Properties considered.	Structural steel.	Rivet steel.
Tensile strength, in pounds per square inch	55 000—65 000*	46 000—56 000
Yield point, minimum, per square inch	0.5 tensile strength	0.5 tensile strength
Elongation in 8 in., minimum percentage	$\frac{1\,500\,000}{\text{Tensile strength}}$†	$\frac{1\,500\,000}{\text{Tensile strength}}$
Elongation in 2 in., " "	22	.....

* See Article 706, Paragraph (*b*).

† See Article 707.

(*b*).—In order to meet the required minimum tensile strength of full-size annealed eye-bars, the purchaser may determine the tensile strength to be obtained in specimen tests; the range shall not exceed 14 000 lb. per sq. in., and the maximum shall not exceed 74 000 lb. per sq. in. The material shall conform to the requirements as to physical properties other than that of tensile strength, specified in Articles 706(*b*), 707(*b*), and 708(*b*).

(*c*).—The yield point shall be determined by the drop of the beam of the testing machine.

707.—Modifications in Elongation.—

(*a*).—For structural steel more than $\frac{3}{4}$ in. in thickness, a deduction from the percentage of elongation in the 8 in. specified in Article 706(*a*), of 0.25% shall be made for each increase of $\frac{1}{32}$ in. of the specified thickness above $\frac{3}{4}$ in., to a minimum of 18 per cent.

(*b*).—For structural steel less than $\frac{5}{8}$ in. in thickness, a deduction from the percentage of elongation in the 8 in. specified in Article 706(*a*), of 1.25% shall be made for each decrease of $\frac{1}{32}$ in. in thickness below $\frac{5}{8}$ in.

708.—Bend Tests.—

(*a*).—The test specimen for plates, shapes, and bars, except as specified in Paragraphs (*b*), (*c*), and (*d*), shall bend cold through 180° without cracking on the outside of the bent portion, as follows: For material $\frac{3}{4}$ in. or less in thickness, flat on itself; for material more than $\frac{3}{4}$ in. to and including $1\frac{1}{4}$ in. in thickness, around a pin the diameter of which is equal to the thickness of the specimen; and for material more than $1\frac{1}{4}$ in. in thickness, around a pin the diameter of which is equal to twice the thickness of the specimen.

(*b*).—The test specimen for eye-bar flats shall bend cold through 180° without cracking on the outside of the bent portion, as follows: For material $\frac{3}{4}$ in. or less in thickness, around a pin the diameter of which is equal to the thickness of the specimen; for material more than $\frac{3}{4}$ in. to and including $1\frac{1}{4}$ in. in thickness, around a pin the diameter of which is equal to twice the thickness of the specimen; and for material more than $1\frac{1}{4}$ in. in thickness, around a pin the diameter of which is equal to three times the thickness of the specimen.

(*c*).—The 1 in. by $\frac{1}{2}$-in. test specimen for pins, rollers, and other bars, when prepared as specified in Article 709, shall bend cold through 180° around a pin 1 in. in diameter, without cracking on the outside of the bent portion.

(*d*).—The test specimen for rivet steel shall bend cold through 180° flat on itself, without cracking on the outside of the bent portion.

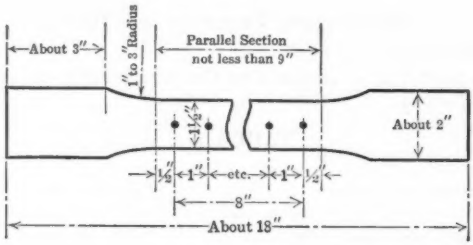

FIG. 4.

709.—Test Specimens.—

(*a*).—Test specimens shall be prepared for testing from the material in its rolled or forged condition, except when it is specified to be annealed, in which case the test specimens shall be prepared from the material as annealed for use, or from a short length of a full section similarly treated.

(*b*).—Test specimens shall be taken longitudinally and, except as specified in Paragraphs (*d*), (*e*), and (*f*), shall be of the full thickness or diameter of the material as rolled.

(*c*).—Test specimens for plates, shapes, and flats may be machined to the form and dimensions shown in Fig. 4, or with both edges parallel; except that bend-test specimens for eye-bar flats may have three rolled sides.

(*d*).—Tension-test specimens for plates and eye-bar flats more than $1\frac{1}{2}$ in. in thickness, and bend-test specimens for plates more than $1\frac{1}{2}$ in. in thickness, may be machined to a thickness or diameter of at least $\frac{3}{4}$ in. for a length of at least 9 in.

(*e*).—Test specimens for bars more than $1\frac{1}{2}$ in. in thickness or diameter may be machined to a thickness or diameter of at least $\frac{3}{4}$ in. for a length of at least 9 in.; or tension-test specimens may conform to the dimensions shown in Fig. 5, in which case the ends shall be of a form to fit the holders of the testing machine in such a way that the load shall be axial. Bend-test specimens may be 1 in. by $\frac{1}{2}$ in. in section.

(*f*).—Tension-test specimens for pins and rollers shall conform to the dimensions shown in Fig. 5. In this case, the ends shall be of a form to fit the holders of the testing machine in such a way that the load shall be axial. Bend-test specimens shall be 1 in. by ½ in. in section.

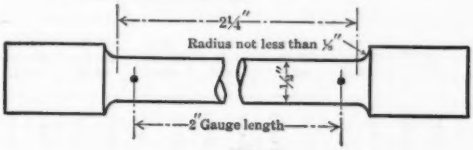

FIG. 5.

(*g*).—The tension-test specimen shown in Fig. 5 and the 1 in. by ½-in. bend-test specimen for pins and rollers shall be taken so that the axis is 1 in. from the surface; and for other bars more than 1½ in. in thickness or diameter, midway between the center and surface.*

(*h*).—The machined sides of rectangular bend-test specimens may have the corners rounded to a radius of not more than $\frac{1}{16}$ in.

(*i*).—Test specimens for rivet bars which have been cold drawn, shall be normalized before testing.

710.—Number of Tests.—

(*a*).—One tension and one bend test shall be made from each melt; except that if material from one melt differs ⅜ in. or more in thickness, one tension and one bend test shall be made from both the thickest and the thinnest material rolled.

(*b*).—If any test specimen shows defective machining or develops flaws, it may be discarded and another specimen substituted.

(*c*).—If the percentage of elongation of any tension-test specimen is less than that specified in Article 706(*a*) and any part of the fracture is more than ¾ in. from the center of the gauge length of a 2-in. specimen, or is outside the middle third of the gauge length of an 8-in. specimen, as indicated by scribe scratches marked on the specimen before testing, a re-test shall be allowed.

IV.—Permissible Variations in Weight and Thickness

711.—The cross-section or weight of each piece of steel shall not vary more than 2.5% from that specified, except in the case of sheared plates which shall be covered by the following permissible variations (1 cu. in. of rolled steel is assumed to weigh 0.2833 lb.):

(*a*).—When ordered to weight per square foot: The weight of each lot† in each shipment shall not vary from the weight ordered more than the amount given in Table 2.

(*b*).—When ordered to thickness: The thickness of each plate shall not vary more than 0.01 in. less than that ordered.

The overweight of each lot‡ in each shipment shall not exceed the amount given in Table 3.

V.—Finish

712.—The finished material shall be free from injurious defects and shall have a workmanlike finish.

---

* The gauge length, parallel portions, and fillets shall be as shown in Fig. 5, but the ends may be of any form which will fit the holders of the testing machine.

† The term "lot" applied to Table 2 means all the plates of each group width and group weight.

‡ The term "lot" applied to Table 3 means all the plates of each group width and group thickness.

TABLE 2.—PERMISSIBLE VARIATIONS OF PLATES ORDERED TO WEIGHT.*

Ordered weight, in pounds per square foot.	Permissible Variations in Average Weights per Square Foot of Plates for Widths Given, Expressed in Percentages of Ordered Weights:

VI.—Marking

713.—The name or brand of the manufacturer and the melt number shall be legibly stamped or rolled on all finished material, except that rivet and lattice-bars and other small sections, when loaded for shipment, shall be properly separated and marked for identification. The identification marks shall be legibly stamped on the end of each pin and roller. The melt number shall be legibly marked, by stamping if practicable, on each test specimen.

VII.—Inspection and Rejection

714.—Inspection.—The Inspector representing the purchaser shall have free entry at all times, while work on the contract of the purchaser is being performed, to all parts of the manufacturer's works which concern the manu-

facture of the material ordered. The manufacturer shall afford the Inspector, free of cost, all reasonable facilities to satisfy him that the material is being furnished in accordance with these specifications. All tests (except check analyses) and inspection shall be made at the place of manufacture prior to shipment, unless otherwise specified, and shall be conducted so as not to interfere unnecessarily with the operation of the works.

715.—Rejection.—

(*a*).—Unless otherwise specified, any rejection based on tests made in accordance with Article 705 shall be reported within five working days from the receipt of samples.

(*b*).—Material which shows injurious defects subsequent to its acceptance at the manufacturer's works will be rejected, and the manufacturer shall be notified.

716.—Rehearing.—Samples tested in accordance with Article 705, which represent rejected material, shall be preserved for two weeks from the date of the test report. In case of dissatisfaction with the results of the tests, the manufacturer may make claim for a rehearing within that time.

Section 8.—Structural Nickel Steel

These specifications conform to the Standard Specifications for Structural Nickel Steel of the American Society for Testing Materials.

I.—Manufacture

801.—Process.—The steel shall be made by the open-hearth process.

802.—Discard.—A sufficient discard shall be made from each ingot intended for eye-bars to secure freedom from injurious piping and undue segregation.

II.—Chemical Properties and Tests

803.—Chemical Composition.—The steel shall conform to the following requirements as to chemical composition:

	Structural steel.	Rivet steel.
Carbon	not over 0.45%	not over 0.30%
Manganese	" " 0.70%	" " 0.60%
Phosphorus, Acid	" " 0.05%	" " 0.04%
Phosphorus, Basic	" " 0.04%	" " 0.03%
Sulphur	" " 0.05%	" " 0.045%
Nickel	not under 3.25%	not under 3.25%

804.—Ladle Analyses.—An analysis of each melt of steel shall be made by the manufacturer to determine the percentages of the elements specified in Article 803. This analysis shall be made from a test ingot taken during the pouring of the melt. The chemical composition thus determined shall be reported to the purchaser or his representative, and shall conform to the requirements specified in Article 803.

805.—Check Analyses.—Analyses may be made by the purchaser from finished material representing each melt. The chemical composition thus determined shall conform to the requirements specified in Article 803.

III.—Physical Properties and Tests

806.—Tension Tests.—

(*a*).—The material shall conform to the requirements as to tensile properties given in Table 4.

(*b*).—The yield point shall be determined by the drop of the beam of the testing machine.

TABLE 4.

Properties considered.	Rivet steel.	Plates, shapes, and bars.	Eye-bar flats and rollers, ‡ unannealed.	Eye-bar flats* and plus,‡ annealed.
Tensile strength, in pounds per square inch	70 000–80 000	85 000–100 000	95 000–110 000	90 000–105 000
Yield point, minimum, in pounds per square inch	45 000	50 000	55 000	52 000
Elongation in 8 in., minimum, percentage	1 500 000 / Tensile strength	1 500 000† / Tensile strength	1 500 000† / Tensile strength	20
Elongation in 2 in., minimum, percentage	.....	.....	16	20
Reduction of area, minimum, percentage	40	25	25	35

*Tests of annealed specimens of eye-bar flats shall be made for information only.
†See Article 807.
‡Elongation shall be measured in 2 in.

807.—Modifications in Elongation.—For plates, shapes, and unannealed bars of more than 1 in. in thickness, a deduction from the percentage of elongation specified in Article 806(*a*), of 0.25% shall be made for each increase of $\frac{1}{32}$ in. of the specified thickness above 1 in., to a minimum of 14 per cent.

808.—Character of Fracture.—All broken tension-test specimens shall show either a silky or a very fine granular fracture, of uniform color, and free from coarse crystals.

807.—Bend Tests.—

(*a*).—The test specimen for plates, shapes, and bars shall bend cold through 180° without cracking on the outside of the bent portion, as follows: For material $\frac{3}{4}$ in. or less in thickness, around a pin the diameter of which is equal to the thickness of the specimen; and for material more than $\frac{3}{4}$ in. in thickness, around a pin the diameter of which is equal to twice the thickness of the specimen.

(*b*).—The test specimen for pins and rollers shall bend cold through 180° around a pin 1 in. in diameter, without cracking on the outside of the bent portion.

(*c*).—The test specimen for rivet steel shall bend cold through 180°, flat on itself, without cracking on the outside of the bent portion.

810.—Drift Tests.—Punched rivet holes pitched two diameters from a planed edge shall stand drifting until the diameter is enlarged 50%, without cracking the metal.

811.—Test Specimens.—

(*a*).—Test specimens shall be prepared for testing from the material in its rolled or forged condition, except when it is specified to be annealed, in which case, the test specimens shall be prepared from the material as annealed for use, or from a short length of a full section similarly treated.

(*b*).—Test specimens shall be taken longitudinally and, except as specified in Paragraphs (*d*), (*e*), and (*f*), shall be of the full thickness or diameter of material as rolled.

(*c*).—Test specimens for plates, shapes, and flats may be machined to the form and dimensions shown in Fig. 4, or with both edges parallel; except that bend-test specimens for eye-bar flats may have three-rolled sides.

(*d*).—Tension-test specimens for plates and eye-bar flats more than $1\frac{1}{2}$ in. in thickness, and bend-test specimens for plates more than $1\frac{1}{2}$ in. in thickness, may be machined to a thickness or diameter of at least $\frac{3}{4}$ in. for a length of at least 9 in.

(*e*).—Test specimens for bars more than $1\frac{1}{2}$ in. in thickness or diameter may be machined to a thickness or diameter of at least $\frac{3}{4}$ in. for a length of

at least 9 in.; or tension-test specimens may conform to the dimensions shown in Fig. 5, in which case, the ends shall be of a form to fit the holders of the testing machine in such a way that the load shall be axial. Bend-test specimens may be 1 in. by ½ in. in section.

(*f*).—Tension-test specimens for pins and rollers shall conform to the dimensions shown in Fig. 5. In this case, the ends shall be of a form to fit the holders of the testing machine in such a way that the load shall be axial. Bend-test specimens shall be 1 in. by ½ in. in section.

(*g*).—The tension-test specimen shown in Fig. 5 and the 1 in. by ½-in. bend-test specimen for pins and rollers shall be taken so that the axis is 1 in. from the surface; and for other bars more than 1½ in. in thickness or diameter, midway between the center and surface.

(*h*).—The machined sides of rectangular bend-test specimens may have the corners rounded to a radius of not more than $\frac{1}{8}$ in.

(*i*).—Test specimens for rivet bars which have been cold drawn, shall be normalized before testing.

812.—Number of Tests.—

(*a*).—One tension and one bend test shall be made from each melt; except that if material from one melt differs ¾ in. or more in thickness, one tension and one bend test shall be made from both the thickest and the thinnest material rolled.

(*b*).—If any test specimen shows defective machining or develops flaws, it may be discarded and another specimen substituted.

(*c*).—If the percentage of elongation of any tension-test specimen is less than that specified in Article 806(*a*) and any part of the fracture is more than ¾ in. from the center of the gauge length of a 2-in. specimen, or is outside the middle-third of the gauge length of an 8-in. specimen, as indicated by scribe scratches marked on the specimen before testing, a re-test shall be allowed.

IV.—Permissible Variations in Weight and Thickness

813.—The cross-section or weight of each piece of steel shall not vary more than 2.5% from that specified; except in the case of sheared plates, which shall be covered by the following permissible variations (1 cu. in. of rolled steel is assumed to weigh 0.2833 lb.):

(*a*).—When ordered to weight per square foot: The weight of each lot* in each shipment shall not vary from the weight ordered more than the amount given in Table 2.

(*b*).—When ordered to thickness: The thickness of each plate shall not vary more than 0.01 in. under that ordered.

The overweight of each lot† in each shipment shall not exceed the amount given in Table 3.

V.—Finish

814.—The finished material shall be free from injurious defects and shall have a workmanlike finish.

VI.—Marking

815.—The name or brand of the manufacturer and the melt number shall be legibly stamped or rolled on all finished material, except that rivet and lattice-bars and other small sections, when loaded for shipment, shall be prop-

* The term "lot" applied to Table 2 means all the plates of each group width and group weight.

† The term "lot" applied to Table 3 means all the plates of each group width and group thickness.

erly separated and marked for identification. The identification marks shall be legibly stamped on the end of each pin and roller. The melt number shall be legibly marked, by stamping if practicable, on each test specimen.

VII.—Inspection and Rejection

816.—Inspection.—The Inspector representing the purchaser shall have free entry at all times, while work on the contract of the purchaser is being performed, to all parts of the manufacturer's works which concern the manufacture of the material ordered. The manufacturer shall afford the Inspector, free of cost, all reasonable facilities to satisfy him that the material is being furnished in accordance with these specifications. All tests (except check analyses) and inspection shall be made at the place of manufacture prior to shipment, unless otherwise specified, and shall be conducted so as not to interfere unnecessarily with the operation of the works.

817.—Rejection.—

(*a*).—Unless otherwise specified, any rejection based on tests made in accordance with Article 805 shall be reported within five working days from the receipt of samples.

(*b*).—Material which shows injurious defects subsequent to its acceptance at the manufacturer's works will be rejected, and the manufacturer shall be notified.

818.—Rehearing.—Samples tested in accordance with Article 805, which represent rejected material, shall be preserved for two weeks from the date of the test report. In case of dissatisfaction with the results of the tests, the manufacturer may make claim for a rehearing within that time.

VIII.—Full-Size Tests

819.—Tests of Eye-bars.—

(*a*).—Full-size tests of annealed eye-bars shall conform to the following requirements as to tensile properties:

Tensile strength, in pounds per square inch...	85 000—100 000
Yield point, minimum, in pounds per square inch	48 000
Elongation in 18 ft., minimum, percentage....	10
Reduction of area, " "	30

(*b*).—The yield point shall be determined by the halt of the gauge of the testing machine.

APPENDIX

Tables 5 to 22, inclusive, and Fig. 6, are submitted in this Appendix, in order to facilitate the use of the Specifications. Because of the fact that two engine loadings are presented, it was thought desirable to furnish working tables for both loadings and a table of coefficients for use in converting E-rating to equivalent M-rating, and *vice versa*.

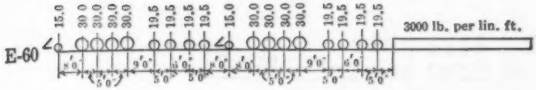
Discussion

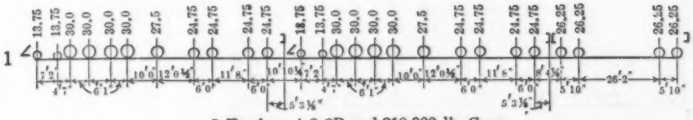
TENTATIVE SPECIFICATIONS FOR STEEL RAILWAY BRIDGE SUPERSTRUCTURE*

By Messrs. F. E. Turneaure, Burton R. Leffler, Francis P. Witmer, James E. Howard, Crosby Miller, C. D. Purdon, G. B. Woodruff, C. E. Conover, Edward Godfrey, D. B. Steinman, Percival S. Baker, A. W. Carpenter, Benjamin W. Guppy, G. G. Thomas, Charles Evan Fowler, Frederick E. Schall, O. H. Ammann, J. B. Hunley, Otis E. Hovey, J. W. Spiller, J. B. French, Henry Goldmark, R. S. Chew, H. M. MacKay, Alfred S. Niles, Jr., and Henry B. Seaman.



F. E. Turneaure,† M. Am. Soc. C. E. (by letter).—As both live loading and impact have been recent subjects discussed by the American Railway Engineering Association, the work of the Special Committee on Specifications for Bridge Design and Construction of the Society, was greatly simplified, and, in general, consisted of a careful review of the publications of that Association and the consideration of new material or new aspects that may have appeared since that time.

Engine Loading.—A detailed study of the relative effects of various engine loadings in use and the standard Cooper series has been published by the American Railway Engineering Association.‡ The most significant of these diagrams are re-published as Figs. 1 to 6, inclusive, and show clearly the relative effects of the Cooper series as compared with engine loadings in use. Of these diagrams, Fig. 1, Group 1, shows seven heavy road locomotives of various types; Fig. 2, Group 2, shows six locomotives, representing the



* Abstracts of discussions on the Tentative Specifications for Steel Railway Bridges presented as a Progress Report of the Special Committee on Specifications for Bridge Design and Construction to the Annual Meeting of the Society, and published in *Proceedings*, for December, 1921, April, May, August, and October, 1922. These abstracts are published in *Transactions* by the authority of the Committee on Technical Activities and Publications as valuable contributions to the subject.

† Cons. Engr.; Dean, Coll. of Mechanics and Eng., Univ. of Wisconsin, Madison, Wis.

FIG. 6.

heaviest of the various types of engines now generally used in special service; Figs. 3 and 4 show the actual moments and shears produced by the loading shown in Figs. 1 and 2, and, likewise, the moments and shears produced by Cooper's E-60 loading; and Figs. 5 and 6 show the moment and shear curves for the locomotives covered by Groups 1 and 2 (Figs. 1 and 2), plotted as percentages of Cooper's E-60 loading.

As a basis of this study, the Cooper series was recommended by the Committee of the American Railway Engineering Association and adopted by that Association. The reasons presented by the Committee were as follows:

1.—No one existing type of locomotive loading gives maximum moments and shears for spans of all lengths, whereas the system recommended does approximate the high points of the curves of all the existing types.

2.—This system of loading produces stresses slightly smaller in short-span bridges and slightly greater in long-span bridges than those produced by the heaviest types in operation, which provides adequately for the engines now in use, and for future development in engine and car loadings which will increase the load per foot on long structures.

3.—This system is the adopted standard of measurement of strength of existing bridges on the majority of roads, and, having been in use for a number of years, conveys a clear picture to engineers and operating officials.

The question of some equivalent uniform load or other simple conventional loading was considered by the Committee, as well as the reasons previously mentioned; but in view of the fact that this problem has been before bridge engineers for many years and has been also discussed at length by the Committee of the American Railway Engineering Association, it was not considered necessary at this time to make an elaborate study of this general problem. The Cooper loading, therefore, was adopted for the reasons already stated.

The standard loading specified by the Committee is Cooper's E-60, but for special cases it is provided that the load may be varied as required by the engineer. This provision is more elastic than that given by the specifications of the American Railway Engineering Association, which state that in no case shall the load be less than E-45. For multiple-track bridges, the percentage reduction for one and two tracks is the same as that given in the specifications of the American Railway Engineering Association; but, for four tracks, the reduction is 30 instead of 25 per cent. Considering the fact that the impact formula is to be applied to each of the four tracks, it was believed that a reduction of 30% for four tracks was entirely safe.

Impact.—The impact formula of the American Railway Engineering Association was first adopted at the meeting of the Association in 1918, and, as a part of the revised specifications, again in 1920. It was based primarily on the impact experiments made by that Association and reported in its *Proceedings* for 1911, 1914, 1917, and 1918. Other experiments considered were those mentioned by Mr. C. W. Anderson in his paper, "On Impact Coefficients for Railway Girders",* read before the Institution of Civil Engineers.

* *Minutes of Proceedings*, Inst. C. E., Vol. CC (1914–15), p. 178, and Vol. CCI (1915–16), p. 301.

In addition to the work of the American Railway Engineering Association, the Committee has also considered the study of the Indian Railway Bridge Committee, 1919-20, and certain English experiments.* The Indian Railway Bridge Committee has been engaged on a series of tests and theoretical studies, but only partial results have been published; thus far, however, they do not indicate any maximum results higher than those of the Committee of the American Railway Engineering Association. The English tests referred to are particularly interesting and valuable because they were made by a recently developed extensometer in which the deformations are magnified by the movement of a mirror and the record is made on a photographic film. This arrangement reduces the inertia of moving parts to a minimum, and should produce a more reliable apparatus, especially for tests on short spans. These tests are also interesting, because many of them were made on very short spans which were not well covered by the tests of the American Railway Engineering Association. The value of some of the published results is considerably affected by the shifting of the zero of the diagram during the test, and because of the great differences between the calculated static stresses and the observed slow-speed values. Comparing these experiments with those of the American Railway Engineering Association, it appears that results for spans of more than 40 ft. are fairly well confirmed by the English tests. On the whole, the English tests show smaller results for these spans than those of the American Railway Engineering Association. For spans less than 30 or 40 ft., the results obtained by the Committee of the American Railway Engineering Association were not generally satisfactory, on account of instrumental vibrations, and in the report of that Committee not much weight was given to results on such short spans. In selecting a formula, the Committee of the American Railway Engineering Association was guided primarily by the results of tests of spans of 30 ft. and more, and for shorter spans by past practice, in which the impact has been taken at about 100 per cent. These considerations resulted in the formula adopted, which gives a reversed curve, starting at 100% for zero span and dropping to 75% for 100-ft. spans. These values are the same as those given by the old formula of the American Railway Engineering Association, and between these span lengths the new formula gives somewhat higher values. For spans exceeding 100 ft., the new formula gives values less than the old one, the difference gradually increasing with the span length.

In discussing the type of formula to be preferred, two main points were considered: First, the proper impact values for short spans, say, up to 25 or 30 ft.; and, second, the proper values for spans longer than about 150 ft. For intermediate lengths, there is little difference between the old and new formulas, and no material change was suggested by any member of the Committee.

For very short spans, the principal results are from the English tests mentioned, which include spans as short as 7½ ft. Two formulas have been

* *Engineering News-Record*, October 20, 1921, p. 642.

proposed by those in charge of these tests, the one preferred being:

$$I = \frac{120}{90 + L}$$

This formula gives 133% impact at zero span and somewhat lower values than the American Railway Engineering Association's curve between spans of 35 and 200 ft., and higher values for longer spans.

Another impact curve which gives a value exceeding 100% for zero span, and which conforms well to the test of the American Railway Engineering Association, is that of Henry B. Seaman, M. Am. Soc. C. E.* This formula is an elliptical curve, tangent to the Y-axis at zero span and to the X-axis at 1 000 ft. span.

Another formula of the same type as the old formula of the American Railway Engineering Association was suggested by a member of the Committee, namely,

$$I = \frac{175}{140 + L}$$

This formula gave an impact of 125% for zero span.

For spans of 200 ft. and more, all experimental results indicate that the old curve of the American Railway Engineering Association is much too high, but naturally there is considerable difference of opinion as to the proper values to adopt.

The desirable type of formula appeared to be dependent on whether or not the impact percentage for zero span was to be made more than 100 per cent. If increased to 125 or 130%, the old type of formula could be made to fit the tests satisfactorily; but if 100% was taken as the value for zero span, then such a curve, if kept high enough for spans of less than 150 ft., would be too high for long spans.

Burton R. Leffler,† M. Am. Soc. C. E. (by letter). For columns, the straight-line formula and the parabolic formula give practically the same average unit stresses. The Rankine formula gives different average stresses. The writer prefers the parabolic formula, if it is necessary to consider a column from a purely empirical standpoint. The parabolic curve fits the tests through the whole range to the point of tangency with Euler's curve. Neither of the other two formulas has this quality; it is necessary to state one or more limits. The writer believes that it is a mistake to consider column tests from a purely empirical standpoint.

It has become the practice to draw a line through plotted results and assume that the equation of the line represents the whole phenomena.

Euler's formula fits the tests for long columns, say, for $\frac{l}{r}$ more than 150, when due consideration is given to the degree of fixation at the ends. A long thin column, such as a sword blade or a steel straight-edge, may fail by pure buckling, with unit stresses below the elastic limit. Euler's formula expresses the law of failure for a straight spring.

* *Transactions*, Am. Soc. C. E., Vol. LXXV (1912), p. 318.

† Engr. of Bridges, N. Y. C. R. R., Lines West of Buffalo, Cleveland, Ohio.

A short column fails because the unit stress at some section exceeds the strength, or the elastic limit, of the material. It does not fail because the average unit stress is high. For very short columns the average unit stress is equal to the highest unit stress. At any section of a column there is an axial force and a bending moment. For short columns the bending moment is zero, or nearly zero, depending on how closely the column is centrally loaded.

The problem of the column is one of bending moment. The very fact that columns fail with an average unit stress below the strength of the material is evidence that it is impossible to centralize the load at every section, regardless of how central the load is at the ends of the columns. This is due to the non-homogeneous character of the material, caused by imperfection of manufacture and fabrication. For like reasons a correct theory of the failure of a tension member includes the consideration of a bending moment. Every structural member in a bridge has a bending moment; in tension members its effect is negligible, whereas, in columns, it is important.

At any section of a column the bending moment may be assumed as caused by the load being eccentrically applied. There may be an additional eccentricity due to the load being visibly non-central at the ends of the column.

As soon as an eccentricity is assumed, a correct column formula can be developed. The formula is:

$$p = \frac{f}{1 + \frac{e\,c}{r^2} \sec \frac{l}{2\,r} \sqrt{\frac{P}{E}}}$$

which is known as the secant formula, and is somewhat cumbersome to apply. p is the average unit stress, e the eccentricity, r the radius of gyration, l the length of the column, and c the distance from the gravity axis to the extreme fiber. The other terms are well known. The formula is for columns having knife-edges (not pins) at the ends. For other end conditions, suitable values of l must be used. The reader is referred to the different treatises on mechanics of materials.

All the terms are determinate for the ideal column; but, for the practical column, visibly centrally loaded, e is unknown; it must be determined by experiments. The results of the experiments must be interpreted, keeping in mind the relations of the other terms of the secant formula.

The second term in the denominator of the formula determines that part of f caused by the bending moment.

A column formula which represents the bending fiber stress without the term, c, must be wrong. The distance to the extreme fiber and the radius of gyration are fundamental terms in any formula which purports to give a bending fiber stress.

The secant formula compels the designer to consider the section of a column in a thorough manner. It is interesting to note that Tredgold and Gordon considered the c term to be important in a column section. Deter-

mining the area of a column section should be something more than a blind use of $\frac{l}{r}$ in a formula.

The writer regards the tests of columns as useless until engineers rationalize the results. The form of the section and the difference between a purely rolled column and a built-up column should be given more study.

Where a problem admits of a partial rational treatment, it seems wrong to solve it in a purely empirical way. Engineers should couple rationalizing and experimenting.

Let us consider further the formulas: Take $\frac{l}{r} = 40$. The fiber stress due to bending is 2 000 lb. for the straight-line formula, 400 lb. for the parabolic formula, and 1 700 lb. for the Rankine formula. As the straight-line and parabola almost coincide, why the difference? The writer will leave this to the reader to think about. If the shear for column lacing is calculated, marked differences will also be found.

The secant formula includes Euler's formula. Arthur Morley deduces the formula by a substitution of terms in the chain of reasoning leading to Euler's formula.*

The secant formula fits the results of tests closer than any other.†

The advocates of the Rankine formula claim that it is rational, but how can it be with the c term omitted? The late J. B. Johnson, M. Am. Soc. C. E., deduced the formula‡:

$$p = \frac{f}{1 + \frac{e\,c}{r^2} + \frac{f - p}{10\,E}\left(\frac{l}{r}\right)^2}$$

The formula is based on the bending diagram as being a parabola; for the secant formula, the diagram is a sinusoid. Rankine's formula is derived from Johnson's formula by omitting the second term of the denominator and substituting an empirical constant for the coefficient of the last term. Such transformation is not valid; it shows Rankine's formula to be strictly empirical. On account of this transformation, the formula does not fit test results as well as the parabolic formula.

A riveted column should be designed for a section less than the gross. Riveted tension members are designed for net section. Probably a somewhat less allowance would do for columns. Riveting should be reduced to a minimum, and should be symmetrical at any section of the column. The ordinary column composed of two channels connected by single lacing is unsymmetrically riveted.

Symmetry should be a cardinal principle in column design, it reduces the unknown eccentricity; minimum fabrication is also conducive to this end.

Francis P. Witmer,§ M. Am. Soc. C. E. (by letter).—In Fig. 7, curves are shown for the following column formulas:

FIG. 7.

The Rankine formula:

$$S = \frac{16\,000}{1 + \frac{l^2}{13\,500\,r^2}} \quad \text{.....(I)}$$

The parabolic formula:

$$S = 12\,500 - 0.25\left(\frac{l}{r}\right)^2 \quad \text{.....(II)}$$

The straight-line formula:

$$S = 15\,000 - 50\,\frac{l}{r} \text{ (max. 12 500)} \quad \text{.....(III)}$$

The straight-line formula:

$$S = 16\,000 - 70\,\frac{l}{r} \text{ (max. 14 000)} \quad \text{.....(IV)}$$

One-half the Euler formula for ultimate strength of round-ended columns:

$$S = \frac{1}{2}\left(\frac{296\,000\,000}{\left(\frac{l}{r}\right)^2}\right) \quad \text{.....(V)}$$

One-half the eccentricity formula for ultimate strength of round-ended columns:

$$S = \frac{1}{2}\left(\frac{32\,000}{1 + \frac{e\,c}{r^2 \cos\frac{l}{2}\sqrt{\frac{P}{E\,I}}}}\right) \quad \text{.....(VI)*}$$

A formula of Rankine type:

$$S = \frac{16\,000}{1 + \frac{l^2}{z\,r^2}} \quad \text{.....(VII)}$$

in which z has variable values, taken so as to produce a curve practically identical with Formula (VI), except that S has a maximum value of 13 000 (below $\frac{l}{r} = 30$).

A suggested straight-line formula:

$$S = 15\,500 - 60\,\frac{l}{r} \text{ (max. 12 500)} \quad \text{.....(VIII)}$$

For Formulas (V) and (VI) the elastic limit is assumed at 32 000 lb. per sq. in. Formula (VI) not only corresponds, theoretically, to a constant initial eccentricity of 0.8 in. (which is about 5% of the depth of the column), but it can also be shown that this same percentage of eccentricity is consistent with a modulus of elasticity of nearly $E + 10\%$, on one side of the column, and $E - 10\%$, on the other side, so that it is also in harmony with a not unreasonable assumption as to variation in E. The curve of Formula (VI) agrees

* In formula (VI), all columns are assumed to consist of two 15-in. channels, 33 lb., latticed, and the eccentricity, e, is assumed at 0.8 in. for all cases.

as well with test results as Formulas (I), (II), (III), or (IV), and has the additional merit of being continuous for all values of $\frac{l}{r}$, blending into Euler's curve for the higher values. The only valid objection to its adoption is the inconvenience of applying it. Formula (VII), therefore, has been devised to give practically the same curve as Formula (VI), but to have the advantage of the Rankine formula as to ease of application, except that the coefficient, z, of r^2, instead of being constant, varies according to a simple law.

If objection is raised on theoretical grounds to a variable coefficient of r^2 in a formula of the Rankine type, it may be met by the argument that the Euler formula, itself, may readily be transformed into a Rankine formula, in which z varies from 13 500 at about $\frac{l}{r} = 171$ to 9 250 at $\frac{l}{r} =$ infinity. Why, then, should not a variable value be considered reasonable for lower length ratios, where Euler's formula is not applicable?

A little consideration will show that the column shear due to assuming the bending to be caused by an initial eccentricity, is less than that due to assuming it to be caused by an initial deflection, and, therefore, to be on the safe side, the latter assumption should probably be made in calculating shearing stresses, although at some sacrifice of consistency. With a column formula of the Rankine type, this assumption will lead to a shear having the value, $V = \frac{\pi P L}{z c}$ (if the curve is assumed to be a sinusoid), P being the total load, L the length, c the distance from the neutral axis to the extreme fiber, and z the coefficient of r^2 in the Rankine formula. Hence, Formula (VII) may be consistently used for calculating column shears.

It cannot be denied that some formula would be desirable, that had a rational form and that would be applicable to higher values of $\frac{l}{r}$ than the limiting ones prescribed in the specifications. Although adherence to these values admittedly would control ordinary bridge design along safe and proper lines, yet there is no doubt that any formula recommended by the Society will be applied on occasion to higher values than those prescribed, as, for example, in investigating the strength of existing structures, or in the design of special structures, such as transmission towers; and the formula recommended should not lead to results either dangerous or unduly on the safe side. Formula (II) would produce the latter result, and Formula (III), the former, if pushed to extremes. Formula (I) would be fairly conservative, but its curve lies considerably above that of Euler for higher length ratios, and this makes its use in such cases questionable. Undoubtedly, Formula (VI), or its simpler equivalent, Formula (VII), would be preferable, if it were not considered too difficult of application.

If a straight-line formula was adopted finally, it would seem that it should lie somewhere between Formulas (III) and (IV), as, for example, a line passing through $S = 12\,500$ at $\frac{l}{r} = 50$, and drawn tangent to Euler's curve, V.

Formula (VIII) is suggested as approximating these conditions. Its results would not differ materially from those of Formulas (I), (II), or (III), for ordinary length ratios, and it could safely be used up to $\frac{l}{r} = 200$, as it does not depart materially from Euler up to that point.

In conclusion, the writer wishes to emphasize once more the suggestion that the formula adopted by the Society should be one which can be properly used by engineers, with a minimum of reservations as to its applicability, because it may be safely predicted that it will be extensively used on its own merits, entirely apart from the general body of the specifications, in view of its authoritative source, and, therefore, it should not be in any degree misleading.

JAMES E. HOWARD,* ESQ. (by letter).—Referring to the subject of column formulas, it appears to the writer fundamentally desirable to restrict the length of columns when feasible to do so. The failure of a column, if it occurs, is likely to be the result of an emergency, such as being called on to act as a collision strut.

The manner of failure in the last stages of long and short columns differs. A period is reached in the failure of a long column when sudden lateral deflection, or springing, occurs, attended with great loss in resistance. If, perhaps, a long column was forced out of line a certain distance, collapse of the structure would certainly follow. A sudden drop in sustaining power is not characteristic of a short column.

Concerning column formulas, the writer has been forced to take a position at variance with prevailing views, raising the question whether, in practice, they are what they purport to be.

An early series of tests on Phœnix columns was made by the writer, the results of which have been reported to the Society by Messrs. Clarke, Reeves, and Company.† Certain queries arose during the making of these tests, which led to making another series soon thereafter on plain square bars. The latter measured 3 in. on a side, were tested chiefly with pin-ends, and were of different ratios of slenderness.

At the time of these tests, few modified column formulas had been presented, those of Euler, Rankine, or Gordon being in use. A feature was brought out in the tests of the square bars, not peculiar to these small members, but common to structural shapes, which seemed to militate against any formula except a purely empirical one, namely, the presence of a state of internal strain which arose from two causes, the cooling strains of fabrication, and those set up by cold straightening. Although the investigation of these internal strains was not undertaken until some years later, when numerical values could be assigned them, nevertheless the importance they played was then quite evident.

It appeared subsequently that internal strains from these two causes differed somewhat. Strains from cold straightening were more likely to influence

* Engr. Physicist, Interstate Commerce Commission, Washington, D. C.

† "Experiments upon Phoenix Columns", *Transactions*, Am. Soc. C. E., Vol. XI (1882), p. 1.

the results of compression tests than cooling strains, considering each separately, and as applied to long columns. The reason for this was that internal cooling strains might and probably would leave a substantial margin between the value of the elastic limit of the metal and their own magnitude. This margin would represent the external stress that the member could endure without taking a permanent set, that a state of residual perfect elasticity of some degree, would remain in the member.

Cold straightening is an overstraining of the metal, in which there is impairment of the elastic limits of tension and compression, in addition to which internal strains are set up by the resilient action of the metal when the straightening force is removed. These internal strains are left in a state of equilibrium, but delicately poised, in which their relations to each other are easily disturbed.

Having these features in mind, it appeared that the elastic limit of a column would vary in different parts of its cross-section, and, as early permanent sets would develop locally, that the strength of a long column in particular would be affected by the state of internal strain of its component parts. Here was a factor, it seemed, that might have an influence on the strength of the column of such degree that the application and use of a formula would be nullified.

Internal strains have no influence on the modulus of elasticity of the metal, except that overstraining is known to lower its value temporarily, but from which there is early recovery. The presence of internal strains leads to the display of early sets, perhaps premature local buckling, and local yielding has its effect on the ultimate strength of compression members. Failure in this manner is not taken into account in a column formula.

Internal strains equivalent to working stresses, according to current practice, can hardly be regarded with indifference in their relation to a column formula, and, not being taken into account, may assist in explaining the recurrence of the discussion of the subject.

CROSBY MILLER,* ASSOC. M. AM. SOC. C. E. (by letter).—The Society should consider the development of a specification using a unit tensile figure of about 23 000 lb. per sq. in., and a live load that would represent the greatest which, in the opinion of the designer, would ever pass over the structure, this live load to be expressed in the Cooper loading. A specification of this type will result in a saving in material, due to the use of a higher unit stress for dead load, and, where no future load greater than E-60 is anticipated, would allow the use of a lighter structure.

C. D. PURDON,† M. AM. SOC. C. E. (by letter).—The following suggestions in regard to specifications for steel railway bridges are offered. The width, center to center, of trusses, should not be less than one-twentieth of the span.

Where there is much snow, the guard-rail bolt should be countersunk flush with the top of the guard-rail; a snow plow may strike it.

---

* Bridge Engr., Chesapeake & Ohio Ry., Richmond, Va.

† Cons. Engr., St. Louis Southwestern Ry., St. Louis, Mo.

Why not take the actual load per foot for ballasted floors? The alternate load of 75 000 lb. on each of the axles on a 10-ft. span equals 15 000 lb. per ft. as a maximum.

The writer thinks it would be better to specify E-10 and to make the lower limit E-45. For many branch lines, engines of about E-25 loading are ample for the loads they have to haul, and E-60 means hauling so much more dead load. The limit of E-45 would take care of such cars as the 50-ft. gondolas of 70 tons capacity, of the Pennsylvania Company.

As the coefficient of expansion for steel is 0.0000065 per degree Fahrenheit, it would seem that the coefficient of the American Railway Engineering Association of 1 in. per 100 ft. is ample.

In connection with impact, it has been stated that some English experiments gave 125% on a length of 7 ft. 6 in. The alternate loading of 75 000 lb. on each of two axles, 7 ft. 6 in. apart, gives more than the regular loading, 25% on a 5-ft. length, reducing to 11% on a 10-ft. length; this, with the impact formula of the American Railway Engineering Association, would give an impact of 125% on 5 ft.

This alternate loading does not affect a length of more than 11 ft. The fact that the American Railway Engineering Association specification is limited to spans of less than 300 ft. seems to have been overlooked.

G. B. Woodruff,* Assoc. M. Am. Soc. C. E. (by letter).—The following suggestions as to detailed specifications for steel railway bridges, are offered:

Rolled beams can be used to advantage up to spans of 35 ft.

In order that the main-track alignment may be kept straight, it is often desirable to build four-track bridges with four trusses.

With heavy rails (135-lb.) and guard-rails, rails and fastenings will weigh more nearly 200 lb. per lin. ft. of track.

The writer believes that economy of design requires the use of a heavy live load (say, Cooper's E-90) and of increased unit stresses. A 50% increase in live load would increase the unit stresses in stringers, hangers, and some web truss members about 50% above the specified values, while the chord members of heavy bridges would be overstressed, say, only 25 per cent.

The lateral force should be 700 lb. per lin. ft., as it is simple to calculate, and will give satisfactory results.

The writer believes that provision for an expansion of 1 in. for every 100 ft. in length is sufficient. He is familiar with a number of bridges where the expansion bearings have been marked to determine the expansion, and believes the figure given is more than sufficient.

It may be called "practicable" to use 8 by 8 by 1-in. angles, with no covers, for a girder flange. The specification that "preferably the angles compose 50% of the flange section and in no case shall the flange cover-plates compose more than 60%", is more definite.

Flange splices are necessary in very long girders, and the writer believes that this specification should be extended as in those of the American Railway Engineering Association.

* Asst. to Bridge Engr., Lehigh Valley R. R., Bethlehem, Pa.

Rules for the rating of old structures have been published recently, which allow a unit stress of 26 000 lb., with secondary stresses not considered. It would seem that the margin between this and a 30 000-lb. yield point is very small. Some railroads are now specifying a 33 000-lb. yield point and practically the same elongation and bending tests.

The writer does not believe that full punched work, for main sections, has any place in a present-day specification for railroad bridges, especially if that metal is to be stressed to 26 000 lb. per sq. in., and considering that, in the bridge shop, workmanship is subordinated to tonnage.

C. E. Conover,* M. Am. Soc. C. E. (by letter).—Relative to bridge design for electric traction: From all information that has come to the writer's attention, cars equipped with direct drive produce but little impact, probably not more than 10% for ordinary speeds. As a matter of fact, probably most of that comes from imperfect track or wheel conditions. It is believed that the impact for such bridges could be reduced so as to be not more than 25 per cent.

In regard to depth and spacing of girders, the writer would suggest for bridges for electric railway operation, with cars operated by direct-drive motors, that the girders might as well be 5 ft., center to center, reducing the strain on the ties. It is his judgment, based on information that has come to his attention, that the impact in the case of such cars is very small. There seems to be little necessity for attempting to eliminate the direct effect of this impact by not having wheels directly over the girders.

Edward Godfrey,† M. Am. Soc. C. E. (by letter).—The impact for bridges to carry electric traction exclusively, is required to be one-third as great as for railroad bridges. In the writer's judgment, an impact allowance of 25% for all members of a traction bridge is sufficient. Impact is due almost, if not, entirely to roughness of the track or unbalanced wheels. The effect of impact on any member has little or no relation to the length of span or loaded portion; it depends on the imminence of the member to the track. In very short spans, the member or girder is naturally closer to the track, and tests show higher impact. There is nothing in test results of impact observations to justify a formula that varies the impact with the span length. The only rational method of taking care of the dynamic effect of rolling loads is one on the order of Cooper's specifications, in which the effect of live load on a member is varied in accordance with the directness of its action on that member. In the matter of traction bridges, it seems that the standard practice of using an impact of 25% of the live load on all members should be used.

If one sits on the bottom chord of a bridge while a 5-ton automobile passes at a great speed over the bridge, and from the same location compares the results with what happens when a horse, pulling a light wagon, trots across, one will be convinced that the suddenness of application of the load has little

* Designing Engr., Transit Comm., New York City.
† Structural Engr., Pittsburgh, Pa.

to do with the dynamic effect, whereas vertical vibration, due to the roughness of the floor or the track, or any other cause, has a large influence.

No column formula can be even approximately correct that fails to take into account imperfections in columns, this is particularly true for structurally permissible columns. Years ago, engineers observed that, in the zone of structurally permissible columns, test results were grouped about a practically straight line and then curved up in the zone of slender columns. On the strength of this, the straight-line formula for columns was urged and, later, generally adopted.

This straight-line formula is suitable because it not only is simple of application, but it also virtually recognizes imperfection in columns, as it comes nearer to an agreement with the strength of commercial compression members than any other formula in use.

Among engineers who favor theory, there seems to be a movement to return to the curved-line formulas. The chief argument for the curved-line formula is the inapplicability of the straight-line formula to slender columns—columns outside the range of structural specifications. If the straight-line formula was shown to give false results within the limits where it is used, this would be an argument against it; but because it fails to give proper results in a field where the use of compression members is forbidden, is no reason for its abandonment.

A formula that would give a "whip-shaped" curve of column unit stresses, that part in the region of permissible structural columns being straight and that in the "slender" zone curving up, would agree best with test results. A curve of this shape would naturally have a complex equation, and its use would impose an unnecessary burden on the computer.

That test results do group around a "whip-shaped" curve has been shown in results published in an article* which is a plea for the revival of the Gordon-Rankine formula.

There is no reason why the straight-line formula should not be used for columns up to the maximum ratio of slenderness permitted in structures, slender compression members, such as posts for transmission towers and struts for aeroplanes, being designed by a formula appropriate to that used in the design of long struts. The Euler formula is the proper formula for this purpose, but it is useless for designing structurally permissible columns.

Tests demonstrate that steel is not as good in compression as in tension. It is not clear why the user of the Gordon-Rankine formula should be allowed a maximum unit stress of 14 300 lb. per sq. in., whereas the user of the straight-line formula is allowed a maximum of 12 500 lb. per sq. in. There is no connection between the type of formula used and the maximum unit stress allowed. It seems well to adopt an upper limit of 12 500 or 13 000 lb. per sq. in.

The unit pressure allowed on concrete masonry is 600 lb. per sq. in., which gives an undue advantage to concrete over limestone masonry which is allowed 400 lb. per sq. in. Bridge seats are seldom grouted or embedded in a manner

* *Engineering News-Record*, March 10th, 1921, p. 431, Figs. 1, 2, and 5.

that would give a true bearing, and for this reason unit pressure should be kept low.

Secondary stresses and bending moments due to deflection of floor-beams may be safely ignored in ordinary structures; in fact, it is doubtful whether they need ever be considered.

Specifications should contain a definite pronouncement on the subject of tension on rivet heads. Inhibition of tension on rivet heads defeats its own purpose, whether that purpose is to secure good design or to prevent such tension. Tension on rivet heads gives rigidity and stability to all riveted structures. Without it, structures would rattle and fall apart; it is this tension that supplies the friction that plays a major part in holding riveted pieces together.

Hardly a design can be made that does not involve some direct tensile stress on rivet heads. Rivets are capable of taking a large amount of tension on the heads and, with proper design, of doing so with safety.

On this subject the following is recommended:

"Tension on rivet heads will be allowed only when the connection is symmetrical and contains at least four rivets. The bending at the heel of connection angles must be considered, as well as the bending on the part to which the detail is attached. When $\frac{7}{8}$-in. rivets are used, the connection angles should be $\frac{5}{8}$-in. metal and the gauge of rivets 2 in. With $\frac{3}{4}$-in. rivets use $\frac{1}{2}$-in. angles and $1\frac{3}{4}$-in. gauge. Additional rivets must be provided to take any shear coming on the same connection."

The writer made a series of tests* which seemed to show clearly that the minimum net area of a bar, measured on a zigzag line, joining rivet holes, is the measure of the value of the bar in tension. Opportunity was afforded to bring evidence to controvert this, but no such evidence was furnished. Tests on riveted seams were cited, but a riveted seam in which the stress originates in the rivets, is quite different from a bar or flat, in which the stress is axial and merely distributes itself around holes cut out of the section.

D. B. Steinman,† M. Am. Soc. C. E. (by letter).—In fixing unit stresses for design, the safe stress for dead load should govern. A basic unit stress of 20 000 lb. per sq. in. would leave ample margin below the elastic limit, and would unquestionably be safe for dead load. Providing for dead load stress at 16 000 lb. per sq. in. is a waste of metal. Years ago, Cooper established 20 000 lb. per sq. in. as the working stress for dead load, and the advance since then in the structural art should justify a reduction and not an increase in the "factor of ignorance."

The difference between the effect of live load and that of dead load should be taken care of by the impact allowance and not by a reduction in working stress. If 20 000 lb. per sq. in. is a safe stress for dead load, it is also a safe stress for live load plus impact.

The provision for future increase in live load should be made by assuming a heavier live load, and not by reducing the working stress. To provide for

* *Engineering News*, May 3d, 1906.

† Cons. Engr., New York City.

probable increase in loading by using a reduced working stress is illogical, and results in an unbalanced design. The live load may increase, but the dead load will not; as a result, the bridge members carrying the largest proportion of dead-load stress will be the most extravagantly designed, and the members carrying the largest proportion of live-load stress will be relatively the most deficient in section. It cannot be disputed that exactly the reverse condition ought to be the objective in proper design. To secure the largest possible margin of strength for increasing loads, with a minimum expenditure of metal, the extra metal should be distributed among the various members in proportion to their live-load stresses. Accordingly, the most economical and best balanced design will be secured by adhering to the principle previously enunciated, namely, the provision for future increase in live load should be made by designing for a heavier live load, and not by reducing the working stresses.

The writer maintains that the working unit stress in tension should be at least 20 000 lb. per sq. in. instead of 16 000 lb., and that the other unit stresses should be increased in the same ratio.

Live Load.—It is disappointing to have the important question of live load overlooked, and to retain the ancient Cooper loading in the proposed specifications.

The Cooper loading does not correspond to modern locomotives, and its retention as a standard for design is unscientific. Its use produces designs that are unbalanced for modern loadings. For instance, the Pennsylvania Railroad N-1-S locomotives are equivalent to Cooper's E-55 for some bridge members and to Cooper's E-76 for others, a range of variation of 38 per cent. The Erie 2-10-2 locomotives are equivalent to Cooper's E-53 for some bridge members and to Cooper's E-70 for others, a range of variation of 32 per cent. Other locomotives, compared by the writer, gave similar ranges of variation. In other words, structures designed for the arbitrary Cooper loading will not be of uniform strength for a given modern locomotive; some of the members in a span will be defective in strength, and some of the spans in a line will be disproportionately weak, in comparison with others, and this difference in strength may be as much as 30 or 40 per cent. A loading that yields such disproportionate results may well be regarded as obsolete. A Cooper engine diagram does not represent modern locomotives, and should not be used for designing modern structures.

An argument advanced for retaining the Cooper loading is that it affords a convenient standard for rating bridges; but the writer maintains that a standard that has become warped to such an extent as to yield results that fail to harmonize by 30 to 40% has outlived its usefulness. A loading should satisfy the following requirements:

1.—It should give results that harmonize closely with the stresses producible by modern heavy locomotives.

2.—It should be heavy enough to provide for the probable future increase in loading during the desired life of structures. Accordingly, it should be

25 to 50% heavier than the average present loading (supposed to be represented by Cooper's E-60).

3.—It should be presented in such form as will yield maximum facility of application and will discourage meaningless refinement of computation.

Impact.—In past American practice, there have been two different types of impact formulas:

1.—Formulas based on the ratio of live-load stress to live plus dead-load stress, $\frac{L}{L+D}$.

2.—Formulas based on the length (l) of load producing the stress.

The writer is convinced that formulas of either class are only partly correct; and that, to be truly scientific and comprehensive, an impact formula should combine both the factors enumerated. In other words, a term of the form, $\frac{L}{L+D}$, should be incorporated in the impact formula.

The inclusion of this factor will make automatic correction for the greater inertia resistance of the heavier sections in a given structure and of the heavier structures in a given line. It will apportion the largest relative additional metal for impact to those members in which the live load bears the largest ratio to the dead load, thus contributing to the longevity of the structure under increasing loads. It will yield results conforming to the principle that impact should be less on bridges with solid ballasted floors than on those with open decks. It will yield a reduced impact for bridges carrying a highway floor in addition to the railway tracks. It will be a partial compensation or incentive for adopting the heavier and more rigid construction in a choice between alternative designs. It will automatically increase the impact tax on very short spans and reduce it on very long spans. Moreover, it will yield a formula applicable without change to all types of structure on a line, instead of requiring different formulas to be used for steel trusses, concrete arches, etc.

The formula recommended in the Tentative Specifications is defective in that it makes no distinction between light and heavy constructions of the same length of span; for instance, it would yield the same impact stresses for bridges with solid decks as for those with open floors. This defect would be remedied, and the other advantages mentioned previously would be secured, if the impact formula was corrected to include the factor, $\frac{L}{L+D}$.

The revised formula, moreover, should conform with observed effects by yielding impacts exceeding 100% for very short spans. Accordingly, the writer would propose the following formula for impact percentages so as to combine the two contributing factors of load length and load ratio:

$$I = \frac{200}{100 + l} \times \frac{L}{L + D}.$$

The values yielded by this formula for open-deck spans of various lengths conform closely to the maximum impact percentages recorded in the American and the English tests. This is shown by Fig. 8, where the graph of impact values calculated by this formula (for open-deck spans), practically coincides with the highest test values recorded from all lengths of spans. For solid-deck spans, the impact values yielded by this formula are appropriately lower. The formula is simple and easy to apply.

Column Formula.—The conditions do not warrant hair-splitting precision in fixing working stresses for columns, and there seems to be little justification for using quadratic formulas when a simple straight-line formula gives essentially the same results. A straight-line formula with a horizontal maximum should suffice.

One important point that has not been provided for in any of the standard specifications, is the difference in permissible stress in columns having different forms of open or closed sections. Closed or box sections are safer against buckling than open sections, and solid diaphragms or cover-plates are more effective than planes of latticing. This difference in value of different forms of section should be represented in the column specification. The column formula should allow a higher working stress for the sections that are known to be safer, so as to offer a premium for the selection of the more substantial designs, instead of encouraging, as the present specifications do, the adoption of open, flaring sections for the sake of economy.

On the basis of a working stress of 20 000 lb. per sq. in. for tension, the writer would recommend that the following working stresses be specified for columns:

For a closed section, or a section with two diaphragms, or a section with one diaphragm and two planes of lattice:

$$22\,000 - 100\,\frac{l}{r} \text{ (maximum, 20 000).}$$

For a half-open section with one cover-plate and one plane of lattice, or a section with one diaphragm without latticing:

$$20\,000 - 100\,\frac{l}{r} \text{ (maximum, 18 000).}$$

For an open section with two or more planes of lattice:

$$19\,000 - 100\,\frac{l}{r} \text{ (maximum, 17 000).}$$

The writer maintains that the adoption of such specifications for column design will be conducive to better and more consistent designing.

If, in addition, it is desired to include in the column formula the extreme fiber distance, c, as urged by Mr. Leffler,* the writer would suggest that the term, $100\,\frac{l}{r}$, in the formulas previously mentioned, be replaced by a term:

$$80\,\frac{l}{r}\,\frac{c}{r}.$$

FIG. 8.

Spacing of Trusses.—Past practice has required a width between centers of trusses of about one-sixteenth of the span, and it seems to be a step in the wrong direction to reduce the prescribed width to one-twentieth of the span.

Pin Stresses.—The safe bending stress in extreme fibers of pins is better represented by $40\,000 - 1\,000\,\frac{l}{d}$, than by a flat value of 24 000.*

Reversal of Stress.—Except for the connections, there is no physical justification for the reversal clause, requiring an increase in section for reversal of stress. It has been defended as a disguised method of increasing the sections of web members for prospective load increase; but this object ought to be accomplished in a direct, straightforward manner by designing the structure for the probable future loading. The greater impact on web members is fully provided for in the impact formula proposed by the writer.

Combined Stresses.—With a basic unit stress of 20 000 lb. per sq. in., the augmentation of the working stress for a combination in which lateral and longitudinal forces are included, may be 20%; and if secondary stresses are also included, the augmentation may be 30 per cent.

Overload.—With a basic unit stress of 20 000 lb. per sq. in., it is assumed that the design load is about 25% higher than the present loadings. Consequently, only 25% increase in live load need be considered in the overload clause. In addition, it should be stipulated that any reversal of resultant stress that may be caused by a 25% increase in live load, should be provided for in the design of the member.

Net Sections.—In 1920, the writer submitted, to the Bridge Engineers' Committee of the New York Central Lines, a specification derived from theoretical considerations and confirmed by experimental results:

"The net section of riveted members shall be the least area which can be obtained by deducting from the gross sectional area, the area of holes cut by any straight or zigzag section across the member, counting the full area of the first hole and a fractional part of each succeeding hole, the fractional part being determined by the formula,

$$1.3 - \frac{P}{G} \text{ (but not to exceed unity)},$$

where P is the pitch (longitudinal) distance, and G is the gauge (transverse) distance from the preceding rivet."

The writer has emphasized the importance of designing bridges for ultimate loads with ultimate safe stresses. The retention of this feature in the specifications adopted by the Society will be an important achievement; it will yield balanced designs conducive to the longest possible life for the structure.

PERCIVAL S. BAKER,† M. AM. SOC. C. E. (by letter).—The Pencoyd formula, which has been largely used during recent years, increases the impact only a small amount on spans of less than 100 ft., but on spans of more than 100 ft.

* See the writer's article, "Higher Stresses for Bridge Pins", *Engineering News-Record*, March 24, 1921.

† Engr. of Bridges and Bldgs., P. & R. Ry., Philadelphia, Pa.

the decrease is marked, amounting to 6% for a 150-ft. span and 20% for a 300-ft. span. A more desirable formula appears to be:

$$I = 125 - \frac{1}{8}\sqrt{2\,000\,L - L^2},$$

which follows the tests closely, increasing the impact considerably on the shorter spans and not decreasing it so much on the longer spans, when compared with the Pencoyd formula. In the writer's opinion, the formula,

$$\frac{300}{300 + \frac{L^2}{100}}$$

is not as good as the Pencoyd formula, but the formula,

$$125 - \frac{1}{8}\sqrt{2\,000\,L - L^2},$$

is better.

As all the column formulas in common use agree well with tests, within the limits allowed in good design, there seems to be no good reason for departing from the straight-line formula adopted by the American Railway Engineering Association in 1906 and 1910, namely, $16\,000 - 70\,\frac{l}{r}$, which has been widely used. The writer would place the upper limit about 13 300, which would correspond with an $\frac{l}{r}$ of 40.

A greater value should be allowed for an angle connected by lug angles than for one connected by one leg only.

A. W. Carpenter,* M. Am. Soc. C. E. (by letter).—It is to be questioned whether end floor-beams are to be preferred. They add to the expense, make back-walls less accessible, are not practicable on ends more than slightly skewed, and the writer never found any necessity for them.

Overload.—The A. R. E. A. Specifications provide, in effect, for a 75% increase in live load without more than 50% increase in the specified unit stresses in web members. Ordinarily, chord members and end-posts of trusses up to a span of 300 ft. will carry a live load increase of 60 to 75% (varying with the length of the span), with an increase of not more than 50% in the designing unit stress. In order that the interior web members may not be stressed more than 50% above the designing unit stresses, with the increase in live load which would increase the corresponding chord unit stresses 50%, the web sections must be increased slightly, and it seems well to require this as it adds comparatively little expense to the structure. The A. R. E. A. Specifications provide for the extreme case of 75% overload. By providing for an overload in interior web members equal that which the chords will carry with the same 50% increase of designing unit stress, the desired end would be attained in perhaps the most satisfactory manner.

* Asst. Valuation Engr., N. Y. C. & H. R. R. R., New York City.

Lateral Forces.—Centrifugal force taken at 6 ft. corresponds closely to the height of the center of gravity of the locomotive.

The writer sees no occasion for formulas more complicated than the straight-line formula. There is one thing in connection with column strength, however, which perhaps has not been considered and which might make a worth while subject of investigation, that is, the effect of impact on columns and compression members. The horizontal "cut-off" of the column formula for low ratios of length to radius of gyration is probably all right for static loads, but for impact it is questionable. The impact effects, as the writer conceives them, are momentary in their extremes. It requires time as well as load to cause a compression failure. The case may well be similar to that of timber beams, as noted hereafter. It may be different with a tension member. To take care of this feature the amount of impact could be made less for compression members than for tension members, although retaining the respective working unit stresses proposed. It seems likely that compression members of ordinary truss bridges are being made disproportionately heavy on this account.

Relative to tension in extreme fibers of timber, the Committee on Timber of the American Society for Testing Materials reported, in 1921, in reference to working stresses in structural timber beams, as follows:

"It is also well determined by the tests that resistance to suddenly applied loads is much greater than to slowly applied or constant loading; therefore, the condition of loading will affect the amount of allowable stress;"

and, also,

"From the above it will be seen that in order to have a rational design it is necessary to state working stresses of different amounts for different kinds of loadings and exposure of timber. As an example, for dense structural yellow pine, the maximum working stress will be 1 100 lb. per sq. in. This is for constant loading and for submerged locations where the timber is constantly wet. In locations in the weather, such as bridges, the allowable working stress for constant loading is 1 400 lb. per sq. in. Under cover, where the timber is always dry, the allowable working stress for constant loading is 1 600 lb. per sq. in."

Also,

"From the tests, it is determined that the resistance of timber is approximately proportional to the speed of loading. For constant loading, the stresses above given are proper, but for sudden loading, resulting in 100% impact, the successive loadings being far enough apart so as to allow reasonable recovery of the timber, the allowable stresses may be doubled (not to exceed 2 800 lb. per sq. in.), the stresses due to this sudden loading being those actually computed from the load with the impact. For other proportions of impact, less than 100%, the allowable working stress may be increased in a ratio equal to the percentage of impact. For dense structural yellow pine, the allowable working stresses would, therefore, be as follows:

1. For wet or submerged locations... $1\,100 + 1\,100\,I$ lb. per sq. in.
2. For exposed locations (bridges)... $1\,400 + 1\,400\,I$ " " " "
3. For constantly dry locations..... $1\,600 + 1\,600\,I$ " " " "

where I is the proportional impact stress."

These quotations from the report of the A. S. T. M. Committee, are given because the writer (who is in no way connected with that Committee)

believes it to be the most rational exposition of the subject he has seen and that it points out the proper method of specifying working stresses for timber, although the constants of the impact factors seem rather high. It will be noted that the A. S. T. M. Committee would allow, for dense structural yellow pine, 2 800 lb. per sq. in. (fiber stress in bending) for live loads with 100% impact, 2 100 lb. per sq. in. with 50% impact, but only 1 400 lb. per sq. in. for all dead load or a sustained live load without impact.

BENJAMIN W. GUPPY,* M. AM. SOC. C. E. (by letter).—A desire on the part of some members to have the Society sponsor some kind of a bridge specification has been noted; but what kind, a working specification or a general specification? A working specification is necessarily narrow. It is a definite set of rules issued by the purchaser in order to obtain the kind of a bridge he wants. It is a part of the contract. It should not be used in Court, except as evidence of what is required under the contract. When prepared by an individual, it is the embodiment of his personal predilections; when prepared by a committee, it is usually a compilation of compromises and is subject to modification by the individual user. A general specification, on the other hand, should be broad. From it the purchaser should be able to draw the necessary inspiration and information to enable him to prepare a working specification for any kind of a bridge at any location. It should furnish the information which would enable a user to determine the maximum safe carrying capacity of his structure, in so far as it is possible to do so. It should be capable of being used in Court as a guide in determining right and wrong in bridge design.

The construction of any bridge requires a minimum expenditure to secure the requisite service and security. Additional expenditures, to obtain increased strength and rigidity, to facilitate maintenance, and to minimize the effects of accidents, are optional with the purchaser. Moreover, the cost of the bridge superstructure is only one unit in the cost of the project, and should be balanced against all other items of cost, in order to obtain the total minimum expenditure. All of which should be recognized and provided for in a general specification.

Span.—What is the necessity of recommending limiting span lengths? Why not state limiting conditions instead? The maximum span for I-beams is determined by three factors: Loads, unit stresses, and section moduli. Their use is determined by these three factors plus relative economy. The purchaser should have the option of substituting built sections for I-beams, in order that the work may not be delayed, or for any other good reason, hence there is no minimum limit for plate girders. The maximum span for plate girders is determined by weights and dimensions that can be handled and shipped to the site, the question of relative economy always being considered, and this includes annual cost as well as first cost. As between riveted and pin trusses, it is a question of economy, rigidity desired, and local conditions controlling erection.

* Engr. of Structures, Boston & Maine R. R., Boston, Mass.

Live Loads.—The use of the Cooper series of engines should be continued for well-known and oft-repeated reasons. The proper E value to use is a matter for individual judgment, based on past experience and an estimate of future traffic development. It is good judgment to use an E value in excess of the equivalent E values of the heaviest engines in service. A recommended percentage of excess could be stated. The proper E values for use on different classes of roads could also be recommended.

Unit Stresses and Materials.—Relative to the appropriate unit stresses to use with different grades of materials, and specifications for these materials: The relation between the various stresses should be such that a bridge will be obtained of uniform strength throughout. Would it not be practicable to write all stresses as functions of T, the axial tensile stress, and then specify the appropriate values of T for the different grades of material.

Expansion Bearings.—The object of hinged shoes is to reduce secondary stresses induced by deflection of the bridge or tipping of the masonry and to prevent the eccentric application of reaction due to deflection of the bridge. If the ends of girders are properly designed with sole-plates of the minimum size necessary to meet the specified stress for bearing of metal on metal, the displacement of the end reaction due to deflection will have no serious results. The requirement is not a necessity as has been proved by the long and successful lives of a large number of bridges not equipped with pin shoes.

The writer believes a minimum span length of 100 ft. is sufficient, except for very shallow or very heavily loaded girders, when a limiting span length of 80 ft. can be specified.

Inclined Bearings.—What valid objection can there be to allowing a short-span plate girder to slide on a plane parallel to the grade instead of on a horizontal plane. If the bridge is on a grade, something must be beveled, if there are no pin shoes. It is simplest to put the bevel in the bed-plates. Suppose the sole-plates are beveled and the bridge arrives wrong end to; it will be necessary to go to a wye or turn-table, or laboriously turn the girder at the site; or suppose, as has happened, it is discovered at the site that all the shoe-plates have been riveted up with the thick ends at the ends of the girders. On the other hand, if a casting has been incorrectly placed, it is easy to jack up and reverse it.

Any clearance diagram included in railway bridge specifications should be presented merely as a recommended diagram to be followed where it does not conflict with the law or in the absence of specific instructions. In thickly settled localities, there necessarily must be modifications in clearance often requiring legislative approval, otherwise the cost of furnishing certain facilities would be prohibitive.

Unless the floor of the bridge is planked, ties should be spaced far enough apart so that one's foot will not get wedged between them. The minimum that can safely be used is about 6 in., and 10-ft. ties are long enough, provided an occasional tie is extended and a sidewalk is built outside the guard-stick. These walks have become common in railroad yards and are being called for more and more frequently by Safety First Committees. A floor

of 12-ft. ties, without a sidewalk, does not afford a good passageway alongside a train, especially when it is coated with snow and ice.

The reduction percentages to be applied to loads for multiple-track bridges should be such that the total live load plus the impact minus the reduction, will not be less than the live load without impact. Such bridges in or near yards and terminals will be loaded on all tracks more frequently than similar bridges on the road.

Referring to unit stresses: After the correct relationship between the various stresses has been determined for each class of material, the question of the actual pounds per square inch to be used can be left to individual judgment.

Should not the combined fiber stress be limited to a tension of 16 000 lb. per sq. in., and the proper reduction be made for compression?

Referring to details of design: There will always be a difference of opinion concerning the value of certain details. In a section on this subject, particularly, a compilation of the varying clauses of different specifications will prove of value, especially if accompanied by a full discussion and explanation of each requirement.

It may be stated that local conditions exert such a great influence on the development of any design that they cannot be ignored in a general specification.

G. G. THOMAS,* ESQ. (by letter).—As the American Railway Engineering Association Specifications of 1910 appear to give economical spans, it is the intention of the writer's Company to continue their use.

The principal reasons for adhering to the 1910 Specifications are:

First.—The impact allowance called for is less for spans of 100 ft. and less than in the 1920 Specifications; this will represent a saving in tonnage, as the Company's bridges are, as a rule, plate-girder spans. The impact allowance in the 1910 Specifications appears to cover amply the actual stresses caused by impact, as far as present experience and experiment show.

Second.—The compression formula and the limiting compressive stress allowed in the newer specifications will give heavier and, therefore, more expensive trusses than the older specifications.

CHARLES EVAN FOWLER,† M. AM. SOC. C. E. (by letter).—The fact is generally admitted that the Cooper loadings are out of date, and are only being retained as a matter of expediency. The adoption of a new system that is logical and that will distribute the metal properly, as between short and long spans, was shown to be feasible, by the writer,‡ in his paper on the "Revision of the Niagara Railway Arch Bridge." The Cooper loadings could still be used as a measuring stick, and it seems presumptuous to state that railroad operating officials could not understand such a change.

The matter of impact is certainly better provided for in the elliptical curve, but for a specification presenting the ultimate, it should also have factors for variable and critical speeds.

* Engr. of Bridges, Atlantic Coast Line R. R., Wilmington, N. C.
† Cons. Engr., New York City.
‡ *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–20), p. 1919.

With a proper loading, full allowance for impact, secondary, and all other stresses, modern unit stresses on a basis of not less than 20 000 lb. per sq. in. for structural steel in tension, should be adopted. The writer believes engineers should go even higher and make it possible for the railways to finance the replacement of large numbers of old and light bridges. The fabricating companies should see the advantage to them and join heartily in such a movement.

The adoption of a column formula must wait on a thorough study of all the recorded test of columns. There are many engineers who believe that such a study would result in the adoption of the Gordon formula, and this may be true. It may be found, however, that a straight-line formula is practically correct; and, even if the formula adopted would prove as complicated as the secant formula, it need not frighten any one, for the unit stresses for various values of $\frac{l}{r}$ can be tabulated.

It does not matter what specifications are written or published, it is likely that each railway or each large system will continue to have its own specification. They will usually modify the specification standardized by a technical society to suit their own needs. The American Railway Engineering Association proceeded with its specification, regardless of the fact that the Society did not join in it; and the writer inquired of O. E. Selby, Jun. Am. Soc. C. E., Chairman of the A. R. E. A. Committee, about a number of things that had come up in his practice, particularly at Niagara, especially as to column formulas, unit stresses, impact, and locomotive loadings. An invitation was received to attend the Committee meeting at Pittsburgh, Pa., which meeting was held, the writer thinks, in October, 1919. The question of a column formula was discussed by F. E. Turneaure, M. Am. Soc. C. E., and about sixteen other Committee members, all of whom agreed that the logical thing to do was to take all the tests on columns, of the past thirty years, and weed out the columns that were poorly designed, poorly tested, or had failed in detail. This would leave the data on good columns, properly tested, from which to plot curves for the different end conditions, and then decide logically what column formulas to adopt, which would be likely to conform with the ideas of some of the discussors, with H. B. Seaman, M. Am. Soc. C. E., and particularly with the belief of George H. Pegram, M. Am. Soc. C. E., that, when such results are obtained, they will agree closely with the Gordon formula. The A. R. E. A. Committee did not carry out this work.

O. E. Hovey, M. Am. Soc. C. E., worked out the lines or formulas for the light and heavy sections from the report of the Special Committee on Steel Columns and Struts; and from the diagram (Fig. 15) that appears in the Niagara paper,* it may be seen that the Gordon formula, as there plotted, and the lines as plotted by Mr. Hovey, are nearly parallel for the central part of the Gordon curve, or from $\frac{40\ l}{r}$ upward; so that some Gordon formula, in the writer's opinion, will finally satisfy every one, and there is no need to worry

* *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919-20), p. 1959.

about the working out of a complicated formula, because it can be tabulated once for all.

The other major matters are unit stresses and locomotive loading. The question of unit stresses for alloy steels is referred to subsequently, but such unit stresses should certainly not be less than two-thirds of the elastic limit of any material used, or on the basis of 20 000 lb. in tension for structural steel.

It may be interesting to give some idea of the investigations being made for the Detroit long-span bridge, which must be largely of alloy steel. Nickel steel and silicon steel are being used very often, and certainly a comprehensive specification ought to cover them and the corresponding unit stresses. At Detroit, the only silicon steel offered was one with an elastic limit of 45 000 lb., and a steel with an elastic limit of 55 000 lb. is required. This was taken up with one of the best metallurgists in the United States. It is very desirable that tests should be made on the series of silico-manganese-molybdenum steels, referred to by Mr. G. W. Sargent before the American Society for Testing Materials, with carbon from 0.10 to 0.55; manganese from 0.45 to 0.75; phosphorus less than 0.04; sulphur less than 0.05; silicon from 1.75 to 2.00; and molybdenum from 0.25 to 0.50.

In the matter of locomotive loading, the A. R. E. A. Committee insisted on adhering to Cooper. The Committee had prepared a number of diagrams (two of which are published in the writer's closure of the Niagara paper*) purporting to show that the Cooper loading was close enough; E-60, however, was as much as 15% too light for the shorter spans and probably 5% too heavy for the longer spans, as compared with actual loadings. The diagrams did prove just what has been brought out in this discussion.

Referring to the matter of impact formula, it was found at Niagara that some loadings gave more than 100% on short spans. Many variations in impact were found on the 550-ft. span, as compared with other data, owing to the fact that impact is due, not only to the sudden application of the load, but also to unbalanced drivers, bad rail-joints, vibration, and all the additions that a strain-gauge, or whatever instrument is used for taking impact readings, will sum up in a total which will cover everything that is deleterious to the structure.

The writer believes that the English formula presented is the best, for a simple curve, that could be developed. C. W. Lloyd-Jones, Chief Engineer, H. E. H., The Nizam's Guaranteed State Railways, India, who came to the United States in 1921, spent some time with Professor Turneaure, and obtained a great many impact data.

Specifications should cover only points of general design and general detail, and sections covering Unit Stresses and Details of Design should be printed in a separate pamphlet for use in the designing, drafting, and templet departments of the railway and bridge companies. Likewise, sections covering the Quality of Materials and Workmanship should be printed in a separate pamphlet for the use of railway purchasing and inspection departments and the shops of the bridge companies; and there should be a third pamphlet on

* *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–20), pp. 2021 and 2023.

Inspection, Painting, and Erection. These sets of rules can then be referred to by number in the general specification.

The general specification then should cover General Designs; Artistic Features; General Data; Loads and Unusual Forces; Unit Stresses; Details of Construction; and Material and Workmanship, in two separate pamphlets; Inspection, Painting, and Erection in detail, or else in a third pamphlet; and Foundations in general, with foundation details, preferably in a separate pamphlet.

Each large railway, or at least each great system, will undoubtedly, as stated, have its own general specification, but there need be no reason for duplicating the matter suggested for printing in the three separate pamphlets.

FREDERICK E. SCHALL,* M. AM. SOC. C. E. (by letter).—The following suggestions are made with regard to railway bridge specifications: Four-track bridges may be built with four trusses, to avoid disturbing the alignment of the two inside, usually main, tracks.

Spacing of Trusses.—The minimum spacing of trusses or girders fixed at one-twentieth of the span seems to the writer not as good as the one-fifteenth fixed in the A. R. E. A. Specifications.

Weight of Materials.—With heavy rails, such as 135 lb. per yd., with tie-plates and steel guard-rails, the weight of rails and fastenings should be increased to 200 lb. per lin. ft. of track.

Impact.—The impact formula of the 1920 A. R. E. A. Specifications should meet the requirements for open-floor bridges, except for spans of 25 ft. and less. For these short spans, a reduction of the unit stress of, say, 1 000 lb. per sq. in., such as was made in some of Cooper's specifications, might be adopted to good advantage, as short spans, stringers, etc., receive the most severe usage under traffic.

For concrete ballasted floor bridges, for which a smaller impact than for open-floor bridges should be expected, a modified formula for impact should be incorporated in specifications, based on the necessary tests.

Overload.—In order to obtain a properly co-ordinated structure under a 50% overload specified, a live load 50% greater, with impact, than is desired for normal conditions, coupled with proportionately increased unit stresses, might be used in determining the sections required for the various parts.

The shearing unit stress in plate-girder and I-beam webs, if correctly stated at 10 000 lb. per sq. in., net section, seems considerably at variance with the A. R. E. A. Specifications, which allow a unit stress of 10 000 lb. per sq. in. gross section. The writer prefers the allowable unit stress based on net section, as this method tends to prevent the over-punching of web-plates.

Strength of Connections.—Connections carrying live-load stress should have a strength equal to that of the members connected, regardless of the computed stress. Connections for laterals and similar members may be proportioned for the calculated stress. Connections should be made as nearly as practical, symmetrical with the axis of the member.

* Bridge Engr., Lehigh Valley R. R., Bethlehem, Pa.

Built Tension Members.—The minimum length of stay-plates for riveted tension members should be specified.

Cover-Plates.—Flange cover-plates need not be fully developed at the theoretical ends. The requirement of the A. R. E. A. Specifications of extending the cover-plates 18 in. beyond the theoretical length seems to be more consistent.

Flange Splices.—Splices for flange members in long girders are generally necessary; the manner of such splicing should be described.

Bents and Towers.—Bents and towers should usually be united in pairs to form towers, but where single bents occur, the columns should have either hinged ends, or the columns and anchorage proportioned for bending due to horizontal forces and temperature stresses.

The yield point, in pounds per square inch for structural steel, in the writer's opinion, should be fixed at 33 000, or at least made 32 500 which would be 50% of the upper limit of the tensile strength requirement.

Class of Workmanship.—For the main sections of railway bridges, subpunched and reamed work, or drilled work, only, should be used, to assure the best results under the present bridge shop methods, where tonnage output plays such an important part.

O. H. Ammann,* M. Am. Soc. C. E. (by letter).—There appears to be no good reason why specifications cannot be written that will cover the entire field of bridge design. There is much common ground in the design of ordinary and extraordinary bridges, and the field of large bridges is practically virgin in so far as common understanding in the fundamentals of design is concerned.

Such specifications should cover the fundamental principles of sound design, load, and stress assumptions, quality of material and workmanship, as applicable to all kinds of bridges, thus allowing a wide margin for the ingenuity and judgment of the designer in the working out of the style, general arrangement, and type of details.

The true purpose of specifications is uniformity in strength. If too narrow and restrictive as to style and type of design, they tend to shackle originality and progressiveness, promote conventionality, and lack the necessary elasticity to adapt themselves to the ever-changing conditions.

Some of the more important features of specifications, on which there appears to be considerable diversity of opinion, are the live load, impact formula, and unit stresses, more particularly the compression formula.

Live Load.—The Cooper engine loading has become a standard by which railroad bridges can be easily gauged as to carrying capacity, and should not be lightly abandoned, unless another engine loading is produced that is more truly representative of the great variety of present and future locomotives.

Compared with any equivalent uniform load, which, after all, must be based on actual weights, any engine loading possesses the not insignificant advantage of conveying to the mind a truer picture of the actual load.

* Cons. Engr., New York City.

In the Cooper loading both the engine concentrations and the uniform train load behind the engines can be adapted, by simple proportion, not necessarily the same for both, to the actual increase in weight of these train units, and the loading has thus sufficient flexibility for all practical purposes.

Impact.—The new impact formula of the American Railway Engineering Association, is an improvement on the old formula, because it results in a justified economy of metal for spans longer than about 100 ft.; but it is less simple and retains the defect of the old formula of giving impact values that are too low for single-load concentrations and short lengths of load, up to about 25 ft.

Mr. Seaman's formula* and the simpler one proposed by Maj. Mount are better in this respect and, for all greater span lengths, give sections (the only proper criterion for comparison) which differ by not more than 5% from those obtained by the proposed formula.

On account of its simplicity, the writer considers Maj. Mount's formula, $\left(\frac{120}{90 + L}\right)$, or a slight modification thereof, much to be preferred to any of the other purely empirical formulas.

All the previously mentioned formulas, if used in connection with a basic unit stress of 16 000 lb. per sq. in., result in a waste of metal in long spans of, say, more than 500 ft. This is not due so much to the impact formula as to the low unit stress, but if a higher unit stress were allowed, the formulas would give too low values for short spans; in other words, the impact formulas and the unit stresses are not properly correlated for all span lengths.

The simple empirical formula, $\frac{200}{100 + L}$, in combination with a unit stress of 20 000 lb. per sq. in., would give good results for all span lengths.

Whichever of the aforementioned formulas may be adopted, the writer would recommend that the length, L, should be taken to mean the aggregate loaded length on all tracks. This will result in a justified economy in bridges with more than one track. Although no comparative test results are available, it is only reasonable to expect that the impact percentage decreases with increasing number of tracks.

Further, on account of the "cushioning" effect of the ballast, it is reasonable to expect, and the English tests, barring erratic results, prove, that the impact in ballasted bridges is considerably less than in open-floor bridges. The writer, therefore, would recommend, pending further investigation, that ballasted bridges be proportioned for only a fraction, say, 75% of the impact allowance in open-floor bridges.

The semi-empirical formula,† of Gustav Lindenthal, M. Am. Soc. C. E.

$$i = \frac{l}{l + d} \cdot \frac{1\,200 + \frac{a}{n}}{600 + 4a},$$

whatever justification its derivation may have, is the only one which takes

* See p. 595.

† *Engineering News*, August 1, 1912.

all the factors mentioned automatically into consideration. In combination with the high basic unit stress of 20 000 lb. per sq. in., it gives reasonable results in all cases.

For single-track bridges with open-tie floor, and spans up to about 500 ft., it results in steel weights that agree fairly well with those of the other formulas. In longer spans, in bridges with ballasted floors, and in bridges with more than one track, it effects a justified saving.

Unit Stresses and Column Formula.—The writer does not favor the use of low unit stresses. He would rather make liberal assumptions for the external forces and possible combinations of such forces, and let the maximum stresses under extreme conditions reach high values (close to the elastic limit in tension members and to two-thirds of the buckling strength of compression members), provided that design and details are excellent in every respect.

It may be apprehended that the indiscriminate use of the proposed low unit stresses for compression, in particular, will result in unnecessary waste of metal. There appears to be no justification for such low unit stresses for properly designed compression members of small values of $\frac{l}{r}$. These low stresses will encourage poor design under cover of a safe margin, rather than result in greater safety.

In the writer's opinion, the old American Railway Engineering Association formula, $16\,000 - 70\,\frac{l}{r}$, in connection with the unit of 16 000 lb. per sq. in. for tension, gives a safe stress for properly designed columns. The specifications should prevent poor design by prescribing suitable reductions in the permissible stress in cases where thin unstiffened webs, flimsy latticing, such as flat lattice-bars, wide unsupported flanges, or composite parts of the section without direct lateral support, are used.

The Rankine formula is unnecessarily complicated. Its apparent scientific form is not justified, because the law of proportionality, on which its derivation is based, does not apply to the process of buckling of short columns, as the fiber stresses exceed that limit long before actual buckling takes place.

For long columns, with $\frac{l}{r}$ greater than the practical limits, Euler's formula is the only correct theoretical formula. It would be applicable also to shorter columns if the modulus of elasticity was introduced as a variable value for stresses greater than the limit of proportionality. In that form, it proves the fact that the buckling strength of a very short column $\left(\frac{l}{r} = 0\right)$ is identical with the yield point, that is, the stress for which the modulus of elasticity in steel becomes zero.

For intermediate values of $\frac{l}{r}$, which comprise the entire range of practical values, a purely empirical formula and, as the simplest form of such, the straight-line formula appears to be as good as any other.

J. B. HUNLEY,* ESQ. (by letter).—Materials and workmanship have been highly developed, and little difference of opinion can exist as to these requirements in specifications; but there are various ideas as to the type of live load and impact formulas which should be used, and the allowable intensity of working stresses, particularly for columns or struts.

Live Load.—It is admitted that the Cooper loading does not closely conform to any type of engine actually in use, but nothing better has hitherto been devised, and its use has become so general, not only for the design of new railroad bridges, but particularly for the rating of existing bridges and engines, that it is doubtful whether it should be abandoned. It seems to be quite as representative of the modern heavy engine as it ever was of the older and lighter engine, and it is now so firmly established that the time for changing it has probably passed, unless there is in the future some radical change in engine or car design.

Impact Formula.—It is possible that a formula should be used providing more than 100% impact for short spans. Some recent experiments indicate that such high impact stresses exist, but, unfortunately, few tests have been made with American equipment. It is quite probable that, even under average conditions of track and equipment, the impact stress on short spans exceeds the live load; and tests in sufficient number should be made in order to arrive at some correct formula.

It has been contended that the special loading for short spans, consisting of two or more heavy concentrations, safely provides for impact stresses in excess of 100%, but this may be questioned. It is a well-known fact that individual axle loads of locomotives may, and frequently do, exceed the average or assumed axle load by as much as 40 or 50%, with improperly adjusted spring hangers, and the specified concentrated loads can do little more than provide for this contingency.

Column Formula.—The straight-line formula has little to recommend it, except its simplicity and the fact that it does fit, with some accuracy, the results of tests. The second term means little, mathematically, but is merely an approximation of the decrease in strength resulting from an increase in length. It is theoretically incorrect, as its values form a straight line, whereas the actual values must approximate a reverse curve. The values representing the strength of a steel column would not continue horizontally along the line, representing the yield point of the material, to an intersection with the Euler curve, but would drop off between points representing the actual and apparent yield points before it intersected the Euler curve, even if no bending was introduced before the critical load was reached. This results in a reversed curve which, for the actual column, is accentuated by its inherent defects, eccentricities, etc.

Other formulas, more rational, giving accurate results and but little more difficult of application, are available. The mere computation of the permissible working stress in a column is a small part of the careful design or thorough investigation of such members, and if the straight-line formula has no particular merit other than ease of application, it is time to discard it.

* Engr., Bridges and Structures, C. C. C. & St. L. Ry., Cincinnati, Ohio.

The parabolic formula, $p = 12\,500 - 0.25\left(\frac{l}{r}\right)^2$, has much in its favor and, although it is purely empirical, it fits closely the plotted results of tests and is about as easy to apply as the straight-line formula for all ordinary values of $\frac{l}{r}$ less than 160 or 170, where, as often written, $13\,000 - 0.25\left(\frac{l}{r}\right)^2$, it becomes practically tangent to the Euler curve. It would appear that 13 000 could be used safely for the first term of this formula, instead of 12 500. When this value is used and the results are multiplied by 2.5, it will be seen that the curve falls well within, or even below, the averages of tests of pin-end columns.

The Rankine formula, $p = \frac{16\,000}{1 + \frac{l^2}{13\,500\,r^2}}$, if multiplied by the factor 2.5, representing a yield point of 40 000 lb., becomes tangent to the Euler curve, $\frac{16\,E}{\left(\frac{l}{r}\right)^2}$, when the ratio of l to r is about 300. It gives too high values of p, for values of $\frac{l}{r}$ from 0 to 75, and too low values between 90 and 250. This has been the principal objection to this formula. The factor in the second term of the denominator cannot be adjusted to make the curve fit the tests for all values of $\frac{l}{r}$. The curve of this formula, as shown by Mr. Seaman,* is made to fit the average results of tests on flat-end columns, by multiplying the formula by the factor 2.25. This does not make the curve tangent to the Euler curve, and it assumes the yield point of the material as 36 000 lb., when it is probably nearer 40 000 lb.

It seems to the writer that the secant formula is well worth consideration. It is theoretically correct for all lengths of the ideal column centrally or eccentrically loaded, and by the assumption of one factor will properly provide for any inherent eccentricities and defects of the column. With very small values of $\frac{l}{r}$, the working stress approaches the allowable fiber stress and, with increasing values of $\frac{l}{r}$, the formula approaches the Euler formula, which is known to be correct for long slender columns.

Its curve follows closely that of the parabolic formula, for columns centrally loaded, but contains a factor for eccentrically loaded columns; and, for such columns, the term, c, representing one-half the width, takes into account, to some extent, the shape of the section.

The formula as usually written is:

$$p = \frac{f}{1 + \frac{e\,c}{r^2} \times \sec.\ \frac{l}{2}\sqrt{\frac{P}{E\,I}}} \qquad \text{(IX)}$$

* See p. 597.

which may be written:

$$p = \frac{f}{1 + \frac{e\,c}{r^2} \times \sec. \frac{l}{2r}\sqrt{\frac{P}{E}}} \quad \text{.....(X)}$$

in which,

P = load on column;
A = area of column section;
$p = \frac{P}{A}$, average stress;
f = working stress;
e = eccentricity of application of load;
c = distance from neutral axis to outer fiber.

An examination of Formula (X) indicates that when $\frac{l}{r} = 0, p = f$, where there is no eccentricity. As $\frac{l}{r}$ increases, $\frac{l}{2r}\sqrt{\frac{P}{E}}$ approaches the value, $\frac{\pi}{2}$, and the formula becomes the Euler curve, when there is no eccentricity. It also indicates that p does not increase in the same proportion as f.

In using the ordinary column formula for an eccentrically loaded column, the average stress is, $p = \frac{f}{1 + \frac{e\,c}{r^2}}$, whereas, in Formula (X), the term, $\frac{e\,c}{r^2}$, is multiplied by sec. $\frac{l}{2r}\sqrt{\frac{P}{E}}$.

This formula is not widely used, and has apparently not received the consideration it deserves, perhaps for the reason that it is more difficult to apply than many other formulas. By expanding the secant term and using only the first two terms of the series, the formula may be simplified, and becomes:

$$p = \frac{b}{2} \pm \sqrt{\left(\frac{b}{2}\right)^2 - C} \quad \text{.....(XI)}$$

in which,

$$b = \frac{8\,E}{K^2}(1 + a) + f$$

$$C = \frac{8\,E}{K^2} \times f$$

$$K = \frac{l}{r}$$

a = some value, including $\frac{e\,c}{r^2}$, where known eccentricity occurs, and a factor to provide for unknown eccentricity and defects, and for the condition at end of column, whether pivoted, hinged, or fixed.

It may be said that the formula is now only an empirical one, with a value, a, selected to form the desired curve. Although it is not so easily recognized, it still contains the bending factor. When the third term of the expansion

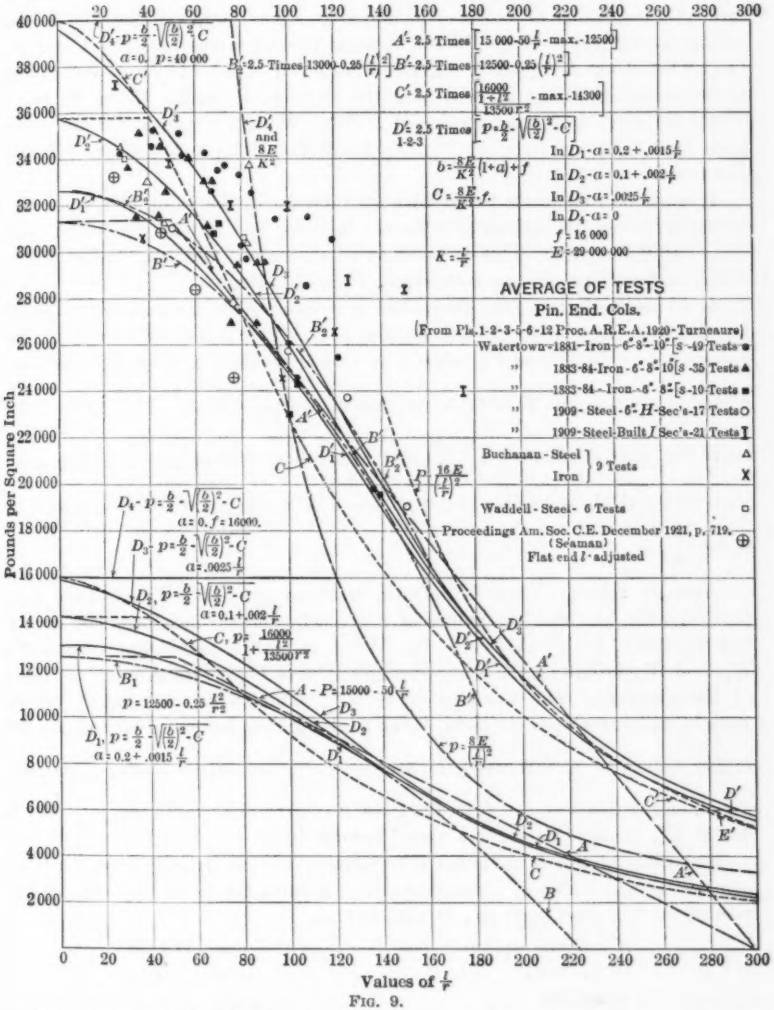

FIG. 9.

series is included, slightly different values of p are obtained, but the equation becomes more complicated and its inclusion is scarcely justified for any practical purpose; but with tabulated values of $\frac{8E}{K^2}$, $\frac{8E}{K^2} \times f$, etc., the formula in this suggested form is not forbidding enough to condemn it.

The values of p (with $E = 29\,000\,000$ and $f = 16\,000$) and with values of $a = (0.2 + 0.0015\ K)$, $(0.1 + 0.002\ K)$, and $(0.0025\ K)$, have been plotted on Fig. 9 (Curves D_1, D_2, D_3), with three other formulas. Curve D_1 ($a = 0.2 + 0.0015\ K$), practically coincides with the parabolic formula through a long range of values of K, and gives a maximum value of $p = 13\,000$, corresponding to the parabolic and straight line maximum values. Curve D_2 ($a = 0.1 + 0.002\ K$) gives a maximum value of about 14 000, corresponding to the maximum value allowed with the Rankine formula. Curve D_3 ($a = 0.0025\ K$) gives a maximum value of 16 000. When the values of p are multiplied by 2.5, the curves, D'_1, D'_2, D'_3, touch the Euler curve, when K equals 200 to 250.

It must be remembered that with an increase in the value of f from, say, 16 000 to 40 000, the values of p do not increase in the same proportion with the same value of a. This is peculiar to the secant formula, and is due to different functions of p in both sides of the equation.

It is interesting to note that when a is assumed to be zero, which would be the case for ideal pivoted columns, and $f = 16\,000$ (Curve D_4), the values of $p = 16\,000$ until a value of $K = 120$ is reached, where the curve becomes $\frac{8\,E}{K^2}$, or, if $f = 40\,000$, the curve becomes $\frac{8\,E}{K^2}$ with $K = 76$. The Euler curve for pivoted columns is $\frac{10\,E}{K^2}$, and if the other terms of the expansion series were retained, the curve for larger values of K would more nearly approach or equal $\frac{10\,E}{K^2}$.

Average values of the Watertown tests on pin-end columns have been plotted, with 2.5 times the values of p given by the various formulas, including the curve, $B'_2 = (13\,000 - 0.25\ K^2)$. It will be noted that Curves D'_1, B'_1, and B'_2, fall along the lower averages; Curve D'_2 passes through the mean of the averages. The Rankine curve, C'_1, exhibits its well known defect, namely, cutting across the field, being high for low values of K and low for higher values of K. When known eccentricity occurs, the term, $\frac{e\,c}{r^2}$, is computed, and if this was, say, 0.25, the term, a (Curve D_1), would become $(0.45 + 0.0015\ K)$, or, for Curve D_3, a would become $(0.25 + 0.0025\ K)$.

The value of this formula for investigating an eccentrically loaded column can best be illustrated by a concrete case. Assume the usual upper chord section of the box type, open on one side, having,

$A = 66.8$ sq. in.	$c = 11.8$ in.
$I = 5\,895$	$e = 2.0$ in.
$r = 9.4$	$\frac{e\,c}{r^2} = 0.267$

The safe load, $P = p\ A$, for the column will be computed by the formula, $12\,500 - 25\left(\frac{l}{r}\right)^2$, and the modified secant formula, using $a = 0.2 + 0.0015\ K$

(Curve D_1), and for values of $K = 50$, 100, and 150. It will be noted from Fig. 9 that the two curves are almost identical for this range of K. The computed values of P are as given in Table 1.

TABLE 1.

Parabolic Formula.				Secant Formula.			
$K = \frac{l}{r}$	$p_1 = 12\,500 - 0.25\left(\frac{l}{r}\right)^2$	$p = \frac{p_1}{1 + 0.267}$	$P_1 = p\,A$	$1 + a$	p	$P_2 = p\,A$	$\frac{P_2}{P_1}$
50	11 875	9 370	625 900	1.542	9 960	665 300	106.3 %
100	10 000	7 890	527 100	1.617	8 190	547 100	103.8 %
150	6 875	5 430	362 700	1.792	5 740	383 400	104.4 %

The secant formula, either in the original or in some modified form, is so rational and has so many good qualities that any discussion of column formulas would not be complete without including it, and the writer can recommend it as an interesting study that, in time, may lead to its more general use, which he believes it deserves.

Table 2 of values of $\frac{8\,E}{K^2}$, $\frac{8\,E}{K^2} \times f$, etc., is included for the convenience of any one desiring to use the formula in this modified form. The values are shown

TABLE 2.—Values of Terms in Modified Secant Formula

$E = 29\,000\,000$ $\qquad$ $b = \frac{8\,E}{K^2}(1 + a) + f$

$f = 16\,000$ lb. $\qquad$ $C = \frac{8\,E}{K^2} \times f$

for values of K, varying by 10; for any intermediate ratio, the value can be obtained by interpolating, with accurate results.

OTIS E. HOVEY,* M. AM. SOC. C. E. (by letter).—It is perfectly proper for the engineer of a railroad to describe in detail just the kind of bridges he may wish to use on his own road; but the writer feels that the Society should attempt to prepare a genuine general specification, laying down such requirements as are vital to good design, suitable materials, proper workmanship and construction, or leave the field to those who wish to express their personal preferences for certain details through the medium of their specifications.

A thoughtful study of the regulations prescribed by law in France might assist one to approach the problem in a manner quite different from that of the Special Committee on Specifications for Bridge Design and Construction. These regulations are of a general character, and a brief paragraph in the second article of the Act of August 29, 1891, states that "these formulas are given as a matter of information only and do not limit in any way the initiative of the engineers, who may employ any method which they may deem expedient", and this refers to as vital a matter as unit stresses.

In this is the nucleus of the whole matter. The Society should endeavor to stimulate and not hamper the development of the best principles of bridge design. The Society should encourage thought, originality, and initiative in its members; but, at the same time, it should be sure to place before them the broad general principles to be followed, and epitomize the experience of the many thoughtful and competent engineers who have given their best efforts to the development of good practice in bridge design and construction.

The writer had intended to limit his discussion to the general principles previously mentioned, but has been requested to present the following method of designing the latticing of compression members. The method is not new, having been used for many years, but may be of value, as it is developed with special reference to the Rankine column formula.

The Rankine column formula, which, in form, is easily derived from the Euler equation, may be stated as follows:

$$\frac{P}{A} = \frac{S}{1 + \frac{l^2}{c\,r^2}} \qquad \text{(XII)}$$

in which,

P = the total axial load on the column,
A = its area,
S = the permissible maximum fiber stress,
l = its length,
r = its radius of gyration, and
c = an experimental constant.

For a short column, $\frac{P}{A} = S$, so it is evident that the expression, $\frac{l^2}{c\,r^2}$, is introduced to provide for bending stresses in a column of material length.

* Asst. Chf. Engr., Am. Bridge Co., New York City.

By solving for S,

$$S = \frac{P}{A} + \frac{P}{A} \times \frac{l^2}{c\,r^2}$$

and the portion, $\frac{P}{A} \times \frac{l^2}{c\,r^2}$, is the allowance for bending expressed in unit stress, or one may write:

$$f = \frac{P}{A} \times \frac{l^2}{c\,r^2} \quad \text{.....(XIII)}$$

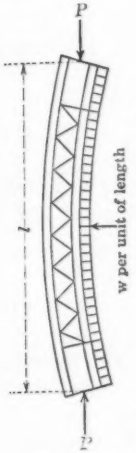

FIG. 10.

A bent column with round ends will take the general form shown in Fig. 10. In order to arrive at a method of calculating lattice bars, it may be assumed as, at least, an approximation, that the forces acting to bend the column under axial load may be replaced by a horizontal unit load of w acting uniformly over the length of the column.

Referring to Fig. 11, the bending moment at the middle of the column will then be:

$$M = \frac{w\,l^2}{8}, \text{ but } R = \frac{w\,l}{2}, \text{ hence } M = \frac{R\,l}{4},$$

and we may write:

$$M = \frac{R\,l}{4} = \frac{f\,I}{y}$$

in which f is the extreme fiber stress due to bending, I is the moment of inertia of the column section, and y is the distance of the extreme fiber from the neutral axis. Replacing I by the equivalent value, $A\,r^2$,

$$\frac{R\,l}{4} = \frac{f\,A\,r^2}{y}, \text{ but } f = \frac{P}{A} \times \frac{l^2}{c\,r^2},$$

hence,

$$\frac{R\,l}{4} = \frac{P\,l^2}{c\,y},$$

and,

$$R = \frac{4\,P\,l}{c\,y} \quad \text{.....(XIV)}$$

FIG. 11.

If Equation (XII) takes the form,

$$\frac{P}{A} = \frac{S}{1 + \frac{l^2}{13\,500\,r^2}}$$

Equation (XIV) becomes

$$R = \frac{4\,P\,l}{13\,500\,y} \quad \text{.....(XV)}$$

R is the calculated shear in the end lattice-bars of the column. If the bars make an angle of θ with the axis of the column and the column is latticed on two sides, the stress in each lattice-bar becomes

$$S_1 = \frac{R \text{ cosec. } \theta}{2} \text{ for single lacing;}$$

and,

$$S_2 = \frac{R \text{ cosec. } \theta}{4} \text{ for double lacing.}$$

The compression formula of the American Railway Engineering Association Specifications of 1910 is $S = 16\,000 - 70\,\frac{l}{r}$. Proceeding in a similar manner, the allowance for flexure corresponding to the term, $70\,\frac{l}{r}$, reduced to shear at right angles to the column is found to be:

$$R = 280\,\frac{A\,r}{y} \quad \text{.....(XVI)}$$

The values of S_1 and S_2 are in the same form as given for the Rankine formula.

The column formula given in the A. R. E. A. Specifications of 1920 is $S = 15\,000 - 50\,\frac{l}{r}$. From this is obtained:

$$R = 200\,\frac{A\,r}{y} \quad \text{.....(XVII)}$$

It will be interesting to compare the values of R obtained from Equations (XV), (XVI), and (XVII), with an actual column. For this purpose, assume a column made up of two channels, 15 in. by 40 lb. per ft. The value of r is 5.43 in. and $r^2 = 29.48$. Assume column lengths from 24 to 40 ft., varying by intervals of 2 ft.; calculate the capacity of the column for each length, and find values of R for each length. The results are given in Table 3.

TABLE 3.

$$S = \frac{16\,000}{1 + \frac{l^2}{13\,500\,r^2}}; \quad R = \frac{4\,P\,l}{13\,500\,y}$$

Length, in feet.	Length, in inches.	$\frac{l}{r}$	S= unit stress allowed.	Area, in square inches,	S= capacity of column, in pounds.	R= shear, in pounds.	Total stress in lattice-bars, in pounds at 45°	Percentage of column stress.
24	288	53.0	13 238	23.52	311 400	3 540	5 010	1.61
26	312	57.4	12 860	"	302 500	3 730	5 280	1.75
28	336	61.9	12 455	"	292 900	3 890	5 500	1.88
30	360	66.3	12 069	"	283 900	4 040	5 710	2.01
32	384	70.7	11 675	"	274 600	4 170	5 900	2.15
34	408	75.1	11 282	"	265 390	4 280	6 050	2.28
36	432	79.5	10 893	"	256 200	4 370	6 180	2.41
38	456	84.0	10 508	"	247 200	4 450	6 290	2.54
40	480	88.4	10 133	"	238 400	4 520	6 390	2.68

From the formula, $S = 16\,000 - 70\,\frac{l}{r}$, $R = 280\,\frac{A\ r}{y}$. Substituting the values from the column previously mentioned, R is found to be equal to 4 470

lb. and the lattice-bar stress at 45° is 6 740 lb., and this value is constant for all column lengths.

From the formula, $S = 15\,000 - 50\,\frac{l}{r}$, $R = 200\,\frac{A\,r}{y}$, hence $R = 3\,410$ lb. and the lattice-bar stress at 45° is 4 820 lb. This is also constant for all column lengths.

The writer feels that it is proper and desirable for the Society to prepare a broad general specification for bridges. Matters of minute detail should be avoided, leaving users of the specifications free to express their own preferences. He believes that such a general specification will be favorably received by the Profession.

There has been quite an extended discussion of various impact formulas, and it may be useful to comment briefly on some phases of the history of their development and use. During the decade from 1880 to 1890, many American engineers began to use the methods of proportioning members that had been developed by Launhardt, Weyrauch, and others, based on the fatigue tests of Wöhler and Bauschinger in Germany and those of Sir William Fairbairn and the late Sir Benjamin Baker, Hon. M. Am. Soc. C. E., in England.

In 1885, the late Joseph M. Wilson, M. Am. Soc. C. E., Engineer of Bridges and Buildings of the Pennsylvania Railroad, issued a specification for wrought-iron bridges in which it was stated that members subject to one kind of stress, all tension or all compression, should be designed for working stresses, a, determined from the formula:

$$a = u\left(1 + \frac{\text{minimum stress in the piece}}{\text{maximum stress in the piece}}\right)$$

Members subject to reversing stresses were designed for working stresses:

$$a = u\left(1 - \frac{\text{maximum stress of lesser kind}}{2 \times \text{maximum stress of greater kind}}\right)$$

The value, u, depended on the kind of iron used, and was 7 000 lb. per sq. in. for single-rolled iron plates and shapes in tension, and 7 500 lb. per sq. in. for double-rolled iron in tension, for links and rods.

Although this method of designing produced a satisfactory distribution of material, it was cumbersome, as each member and its details and connections, including rivets, required the use of a working stress, a, peculiar to the member. As a result of this fact, various attempts were soon made to apply corrections to the calculated stresses, so that by the use of a constant unit stress basis per square inch, the same, or a closely similar, distribution of material would be accomplished. These adjustments of the calculated stresses were called "impacts", but the writer believes they had little or no reference to impacts due to the passage of moving loads. The formula* developed by the late Fred Thompson, M. Am. Soc. C. E., and first published in the specifications of the Southern Railway Company in 1894, was in the familiar form,

$$I = S\,\frac{300}{L + 300}$$

* See discussion by J. B. French, M. Am. Soc. C. E., *Transactions*, Vol. LXXV (1912), pp. 363 to 370.

This convenient formula was at once adopted by the late C. C. Schneider, Past-President, Am. Soc. C. E., as simpler and more satisfactory than his own, and has been generally used in the United States, Canada, and India for many years.

The writer feels that it was unfortunate that the stress adjustment was called "impact", and this term may have misled some users of the method not fully advised of the history of its development.

In 1908, the writer prepared a specification for bridges based on the fatigue method of design, and found that by making the value of u, in the Pennsylvania Railroad formula of 1885, equal to about 9 000 lb. per sq. in. for structural steel, the areas of the main members of single-track bridges, up to 200 ft. span, became almost identical with those of the same spans designed by the use of the "impact" formula, previously given, using unit stresses based on 17 000 lb. per sq. in. This fact tends to confirm his belief that, for practical purposes, the use of the so-called "impact" formula,

$$I = S \frac{300}{L + 300}$$

is mainly a convenient method of distributing the material in a bridge in order to conform practically to the fatigue method of design.

The real test of good design is the behavior of bridges under heavy traffic. When long service and low maintenance costs are considered, the writer believes that bridges designed by the fatigue method have been more satisfactory, on the whole, than those designed by most other methods. In view of the recent fatigue experiments, and studies now being conducted, he feels that this subject should be carefully considered in connection with the many observations of impact due to passing loads now available, before the definite adoption of a new impact formula.

J. W. Spiller,* Esq. (by letter).—A Sub-Committee of the British Engineering Standards Association, of which the writer is a member, is, at present, drafting a specification similar to the Tentative Specifications. In the first place, this Sub-Committee prepared a specification covering "Materials and Workmanship", and then divided into panels to deal with: (*a*) Loads; (*b*) Stress Units; and (*c*) Details of Design and Construction. The writer was placed on the panel dealing with "Details of Design and Construction".

The writer will confine his comments to questions of material, workmanship, and the details of design and construction.

Referring to the "nominal diameter" of a rivet: In Great Britain, there is a difference of opinion, particularly between bridge builders and shipbuilders, as to the exact point on the tapered shank where the diameter should be measured. It might be well, therefore, to define clearly the "nominal diameter".

It has also been stipulated that "connections shall have a strength at least equal to that of the members connected, regardless of the computed strength". This appears to require some qualification in the case of members which are in compression where the strength of the member will depend on the value

* Deputy Chf. Engr. for Design, Crown Agts. for the Colonies, London, England.

of the ratio, $\frac{l}{r}$, whereas the strength of the connections will b independent of this ratio.

Limiting Thickness of Metal.—Some differentiation might be made perhaps between plates, etc., which are accessible for painting on one side and those which are accessible for painting on both sides.

Pitch of Rivets.—The maximum pitch proposed seems to be too great to insure that no corrosion will take place between the parts connected.

Splices.—The gross area of the splice material proposed, namely, 50% of the gross area of the smaller member, does not appear to the writer to be sufficient.

Stiffeners.—The Tentative Specifications do not permit the use of T-beams which make a suitable and economical form of stiffener for small spans.

Camber.—The writer is inclined to think that it is better practice to make the camber equal to the deflection produced by both dead and live load. If, then, one-half the camber due to live load is taken out by notching the sleepers, the level of the rails at the span center will be lower than that at the support by an amount equal to one-half the deflection due to live load when the bridge is loaded and will be higher by a similar amount when the bridge is not loaded.

Punching.—The limits of thickness for punching appear to be on the high side for first-class workmanship.

Web-Plates.—The large clearance allowed between ends of web-plates, namely, $\frac{3}{8}$ in., does not appear to be quite consistent with first-class workmanship.

No reference is made in the specification to the supply of service bolts which should be provided by the bridge fabricator, whether or not his contract includes erection at site.

The writer should like to add that the foregoing comments are not advanced in a spirit of criticism. The Special Committee on Specifications for Bridge Design and Construction has submitted a valuable specification and it is with considerable diffidence that the writer has ventured to draw attention to a few small matters of detail which appear to differ from what would be considered first-class practice in Great Britain.

J. B. French,* M. Am. Soc. C. E.—Many matters of detail are specified rigidly, which, under certain conditions, cannot be complied with and which, in other cases, should preferably be left dependent on the conditions of the particular case. As an example of a requirement impossible of general observance, the clearance diagram may be cited. The clearances specified, which are intended to clear a brakeman on the top or side of a box car, are desirable where practicable, but in grade separation work in large cities, such clearances would involve unwarranted expense. An alternative diagram should be given to cover the latter conditions. Again, the one live load rigidly specified is an example of a matter that should be left more flexible for the reason that many railroad structures, particularly in and around cities, are used almost exclusively for passenger traffic, which is much lighter than the E-60 loading

* Cons. Engr., New York City.

specified. If that loading is retained, the words "unless otherwise specified" should be inserted.

In regard to impact, the speaker is less concerned with the exact form of the formula used to establish the relation of impact to length of span than he is with the principle that the ratio of live to dead load shall be taken into account in its application. Some years ago, he was called on to design a large number of railroad bridges within city limits where solid floors were necessary and where fully ballasted tracks and concrete slab floors were considered desirable. In the preliminary studies, it soon became evident that, unless the usual rules of design as regards unit stresses and impact were modified, this extra dead load would materially increase the weight of the main structures and increase their cost when compared with the old type of open-deck bridges. Considering the cushioning effect of the ballast and the added stiffness and solidity contributed by the concrete, which was thoroughly bonded to the steelwork, it seemed justifiable to modify the specifications by taking these facts into consideration and thereby reduce the weight of the steelwork. The following clause, therefore, was inserted in the specifications:

"In the case of main girders or trusses, and their supports, carrying fully ballasted track, one-half the dead load stress shall be subtracted from the full live load stress, before applying the impact formula."

It seems pertinent to state that the bridges designed in this manner have now been carrying very heavy freight traffic for more than 15 years and, at present, show no signs of weakness. The speaker would continue to use such a rule of design under similar conditions to-day.

The speaker believes that the unit stresses to be used in structural design should be determined by the known physical properties of the material rather than by the character of its use, and that variations in the conditions of use should be provided for logically by corresponding variations in the assumptions of the external forces to be resisted.

The unit stresses in the Tentative Specifications were based on 16 000 lb. per sq. in. for axial tension. This value has in its favor the fact that in recent years it has been adopted, not only in specifications for railroad bridges, but also in specifications for highway bridges and for the structural steelwork of buildings. However, it seems to be too low for all these purposes and the adoption of 20 000 lb. per sq. in. instead of 16 000 lb. would be justified by the known physical properties of structural steel.

A conclusive argument in favor of higher unit stresses is contained in the specifications themselves, in that an overload of 50% is provided for, and the rule, to retain in service existing bridges the unit stresses of which do not exceed 24 000 lb. per sq. in. in tension, is regarded as safe and conservative.

Why not, therefore, increase the live load to E-75, and base unit stresses on a tension of 20 000 lb. per sq. in., or to E-90, and base unit stresses on a tension of 24 000 lb. per sq. in.

The use of structural steel and concrete in effective combination is not referred to. On account of the effectiveness of concrete as a protective covering for steel work, its availability to fill spaces and exclude water, its fire-proof

qualities, and its strength and permanence, its use as a secondary material in the construction of steel bridges has grown steadily in favor and has assumed proportions warranting its consideration in specifications of this kind.

The rules for the design of reinforced concrete have been thoroughly discussed and developed, but where steel is the predominating material and concrete is used to protect and reinforce it, comparatively little has been done to develop or encourage rational design.

It seems obvious that, where concrete is used in combination with structural steel, the more effectively the two are bonded, the more effectively the composite structure will serve its purpose and, if the materials are effectively bonded, the concrete will take its share of the compressive stresses and relieve the steelwork to which it is bonded. Consideration of these facts justify material reductions in the sections of steel parts embedded in concrete and carrying compressive stresses induced after the concrete has set, and substantial economy can be accomplished by corresponding rules of design. The speaker has done this by the use of unsymmetrical beams and girders embedded in concrete, that is, rolled beams with bottom cover-plates only, and plate girders with heavy bottom and light top flanges, and much of the work has stood the test of severe service.

HENRY GOLDMARK,* M. AM. SOC. C. E.—The speaker is much interested in Mr. Hovey's remarks on the historical development of bridge design.† He has always felt that, in an applied science, the study of its evolution is not only of much theoretical interest, but also of direct value in understanding the principles underlying present practice. In the case of bridge engineering, the history of the different methods for taking account of the greater effect of the live loads, especially of train loads, in comparison with the dead weight, is of much interest. Their greater influence on the stresses was realized at an early stage of bridge development, and various methods of design, with this basic idea, have been used at different times.

The earlier methods were frankly empirical, whereas the later ones are based ostensibly on theoretical considerations. It can hardly be said, however, that even the latest practice has an exact scientific basis.

The bridge specifications of the past forty years reflect the varying views held at different periods. In the earliest specification issued by the late Theodore Cooper, M. Am. Soc. C. E., the cross-sections were determined by dividing the sum of the dead and live load forces in each member by a permissible unit stress. To allow for the great effect of live loads in short bridges, a lower stress was specified for such spans. Although many good bridges were designed under this specification, there was a serious objection to this method of proportioning, because of the fact that the unit stress changes suddenly at a given span length, say, from 8 000 to 10 000 lb. per sq. in. Therefore, for bridges differing only 1 ft. or 2 ft. in length, there might be a considerable difference in the permitted stress. This was clearly illogical and led to absurd results, as the longer bridge might actually have a smaller total weight.

* Cons. Engr., New York City.

† See p. 574.

The next step, based to some extent on theory, was to specify a unit stress for the dead load different from that for live loads. For instance, in Cooper's 1902 specification, the permitted live load stresses were half as great as the dead load stresses. This rule was evidently based on the theoretical consideration that a load applied instantaneously has twice the effect of a slowly applied load. It always takes an appreciable time before the stress in a given member, due to a train passing over a bridge, reaches its maximum value. Hence, the rule of halving the live load stress is not correct in theory, although undoubtedly safe in practice.

The next modification, and one that was widely used for some time, was to base the permitted stress on the maximum and minimum forces acting on the members at different times. This method was based on the formula of Professor W. Launhardt of the Royal Polytechnic School at Hanover, Germany. It was confessedly founded on the well-known series of experiments made by Professor Wöhler on the "fatigue" induced in iron bars under a large number of repeated loadings. Although the Wöhler tests were of great value, their application to bridge members, which act under entirely different conditions, was a doubtful step.

Even Professor Launhardt, with whom the speaker had occasion to discuss this matter while taking his course on bridge design, was quite ready to admit this. He was inclined to think that the more empirical methods of simply decreasing the permitted stress in long spans might be the better policy until further investigation should increase the knowledge of the subject. He somewhat whimsically called the exact determination of this question "music of the future".

In American practice, the Launhardt formula and the maximum minimum formula in its various forms have been generally discarded for many years. They have been superseded by the expression for "impact" introduced by the late C. C. Schneider, Past-President, Am. Soc. C. E., in his "Pencoyd" specification, and since then used in the specifications of the American Railway Engineering Association and other technical societies.

In these specifications, the effect of the live load is provided for in each member by an "impact" or "dynamic increment" which contains a term, L, equal to "the loaded length, producing the maximum strain in the member". This, of course, is proportional to the length of time during which the stress in the member gradually increases from zero to its maximum value.

The use of the term "impact" in the A. R. E. A. specification has been much criticized, especially as recent deformation measurements on bridges under service conditions, give somewhat discordant results and seem to show that the effect of live loads has been exaggerated.

It should be remembered, however, that in bridge engineering, as in most other fields of construction, great importance must be assigned to practical experience with structures in actual use, and that, at all times, theoretical considerations must give way to the test of service.

It is not believed that it would be wise to build lighter bridges than those now in use, especially in view of the doubt as to the weight of future engine

and train loads, until much more exact information has been obtained on such important questions as the strength of the newer alloy steels slowly coming into use, the strength of compression members, and the effect of live loads in bridge structures.

R. S. CHEW,* M. AM. SOC. C. E. (by letter).—In a discussion of a paper by Mr. James E. Howard,† the writer called attention to the fact that there is a definite eccentricity in all columns due to imperfections in the member. Although it is probably true that this fact is realized, it has not been given sufficient prominence in various column theories or formulas. The writer does not believe that any theoretical treatment of value can be developed, except in so far as to indicate the various factors that must enter as empiric constants in the working formula.

In order to indicate the action in a column, one is compelled to consider an imperfect member the material of which is not homogeneous in either a horizontal or a vertical plane. Let Fig. 12 indicate a column the imperfections of which are such that the center of resistance is removed from the center of gravity of the section by a distance, e, at the plane of the application of the load and that this distance, e, varies throughout the length of the column.

Let the line, R, indicate this resistance axis. Any number of curves could be drawn to indicate a possible resistance axis, but the one shown indicates the worst condition.

From this line, it may be noted:

(*a*) That all columns are crooked as regards resistance to axial compression.

(*b*) That the resistance axis does not lie in the plane of the principal axes, 1-1 or 2-2, except for circular sections.

Although all theoretical treatments are based primarily on the bending of the column, which, as may be seen, is caused by a crooked axis, yet no one has recognized the condition, (*b*), as the bending has been assumed to take place about Axis 1-1 or Axis 2-2.

Let a theoretical formula be written for axial compression in which:

l = Length (unsupported);
P = Axial load;
A = Area of section;
S = Maximum unit stress on extreme fiber;
r_1 = Radius of gyration about Axis 1-1;
r_2 = " " " " " 2-2;
n_1 = Factor for end conditions about Axis 1-1;
n_2 = " " " " " " 2-2;
$\frac{\phi r}{t}$ = A factor proposed by Lilly.

* Cons. Engr., San Francisco, Calif.

† "Some Tests of Large Steel Columns", *Transactions*, Am. Soc. C. E., Vol. LXXIII (September, 1911), p. 469.

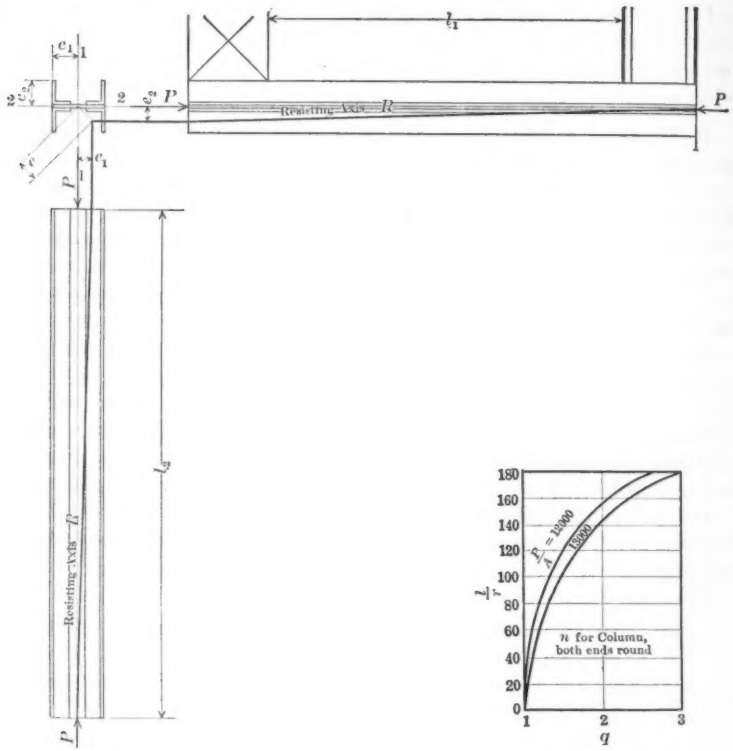

FIG. 12.

FIG. 13.

The formula would appear as follows:

$$S = \frac{P}{A}\left[1 + \frac{\phi r}{t} + \sqrt{\frac{e^2_1 c^2_1}{r^4_1}\sec^2\left(\frac{n_1 l_1}{r_1}\sqrt{\frac{P}{A E}}\right) + \frac{e^2_2 c^2_2}{r^4_2}\sec^2\left(\frac{n_2 l_2}{r_2}\sqrt{\frac{P}{A E}}\right)}\right]. \quad \text{(XVIII)}$$

Equation (XVIII) is of no value except as a study from which, by substitution of empiric constants, a working formula may be derived.

Some of the conditions under which a column acts, as regards Factor n, are as follows:

(1) Pin-ended on Axis 1-1; semi-fixed on Axis 2-2; $l_1 < l_2$; no positive moment, that is, the load is assumed as axial.
(2) Same as Condition (1), except $l_1 = l_2$; no positive moment.
(3) Semi-fixed on both axes; $l_1 = l_2$; " " "
(4) " " " " " ; $l_1 < l_2$ " " "
(5) " " " " " ; $l_1 = l_2$; positive moment, M.
(6) " " " " " ; $l_1 < l_2$ " " "

If r_1 is greater than r_2 and, assuming that the resistance axis does not lie in a plane, Axis 1-1 or Axis 2-2, then the resulting deformation is not that of bending alone, but is bending combined with twisting. Therefore, the combination of end conditions and lengths, l_1 and l_2, and the cross-section of the column must have an important bearing on the resulting stresses. Do either of the submitted formulas take any account of these conditions?

Working Formula.—If, by a series of tests, empiric values could be given to the factors, ϕ, e, and e_2, such that they would represent the average condition in commercial members carrying an axial load and having the various imperfections, Equation (XVIII) would be valuable.

In regard to the factor, n, let:

$$\sec^2\left(\frac{n\,l}{r}\sqrt{\frac{P}{A\,E}}\right) = q \ldots\ldots\ldots\ldots\ldots\ldots (XIX)$$

A series of curves may be drawn for assumed values of n and $\frac{P}{A}$ and for varying values, $\frac{l}{r}$, as shown in Fig. 13.

The formula will then be:

$$S = \frac{P}{A}\left(1 + \frac{\phi\,r}{t} + \sqrt{\frac{e^2_1\,c^2_1}{r^4_1}\,q_1 + \frac{e^2_2\,c^2_2\,q_2}{r^4_2}}\right) \ldots\ldots\ldots\ldots (XX)$$

which, with curves and given values of ϕ, e, and e_2, furnishes a working formula. Equation (XX) can be used in combination with the straight-line formula, that is, by determining a trial section by the following equation:

$$\frac{P}{A} = 15\,000 - 50\,\frac{l}{r}$$

and checking for S in Equation (XX).

The advantages of this formula are that it enables the designer to take care of positive moments and details, to check any damaged column, and to use his judgment between local and expert work for e.

H. M. MacKay,* M. Am. Soc. C. E. (by letter).—The one great object of a column formula is to enable the designer to predict the strength of a column; and possibly the diversity of opinion usually expressed arises from the consciousness that no formula yet proposed is even approximately satisfactory as a means of predicting the strength of a given built-up steel column of ordinary length. Euler's formula is quite satisfactory within the range to which it is applicable, as one may demonstrate with no more elaborate apparatus than a straight lath and a few weights. Rankine, as a reference to his works will show, had in mind solid or relatively thick-walled hollow struts of circular or rectangular section. Apparently, the only modern form which he visualized was a rectangular box-section made up of plates and angles. Both these eminent elasticians, quite justifiably under the circumstances, made the slenderness ratio, $\frac{l}{r}$, the only variable in their well-known formulas; and

* Prof. of Civ. Eng., McGill Univ., Montreal, Que., Canada.

it is perhaps due to the weight of their authority that engineers, in so far as their ideas are expressed in specifications, have continued to regard the slenderness ratio as the only variable. One does not forget the many suggested formulas in which other factors are included, but none of these, as far as the writer is aware, has come into current use, or has, in a broad way, passed the test of satisfactorily predicting column strength.

The most comprehensive series of tests on steel columns of reasonable size is that of the Society's Special Committee on Steel Columns and Struts, reported in 1918.* Three variables were included in the specimens tested: Slenderness ratio $\left(\frac{l}{r}\right)$, form or make-up, and thickness of metal. Considering only those tests in the case of which the complete schedule was carried out, eight different forms were tested, each form with three different values of $\frac{l}{r}$, and two different thicknesses of metal. The heavier sections, on the average, had roughly about twice the sectional area of the lighter sections. Three individual columns were tested for each slenderness ratio, form, and weight, making 144 tests in the group considered. Thus, 48 members of each slenderness ratio were tested, 18 of each form, and 72 each of the lighter and heavier sections. The results of these tests may be tabulated as follows:

A.—In respect of slenderness ratio:

$\frac{l}{r}$	Ultimate strength, in pounds per square inch.
50 (average of 48 tests).....	33 150
85 (" " " ").....	30 650
120 (" " " ").....	28 100

B.—In respect of form or make-up:

Form.	
5– 5*A* (average of 18 tests).....	33 700
8– 8*A* (" " " ").....	31 600
2– 2*A* (" " " ").....	31 000
10–10*A* (" " " ").....	30 400
4– 4*A* (" " " ").....	30 400
3– 3*A* (" " " ").....	30 200
1– 1*A* (" " " ").....	29 100
6– 6*A* (" " " ").....	28 600

C.—In respect of thickness of metal:

Light (average of 72 tests).....	32 200
Heavy (" " " ").....	29 000

The most cursory comparison of these results shows that, as far as these tests are concerned, the influence of thickness of metal on ultimate strength is as great as that of a variation in $\frac{l}{r}$ from 50 to about 95, a range wide enough to include practically all the seriously loaded columns in a steel railway bridge; whereas, the influence of form on the ultimate strength, even neglecting Form 6–6*A* as unusual and undesirable, is nearly 45% greater than that of

* *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–20), p. 1583.

the stated variation in slenderness ratio. Had latticed columns been included in this series of tests, the influence of form might well have been even more pronounced. Tests made for the Board of Engineers of the Quebec Bridge, in part by Mr. James E. Howard, and in part by the writer, indicated that members with solid transverse webs were 11 or 12% stronger, other things being equal, than those in which the ribs were connected by latticing only.

Although the Committee's tests bring out the influence of the thickness of metal in a way that no other tests do, any comprehensive group or groups of tests will indicate a large variation of strength due to form and detail, as compared with that due to a reasonable range in the value of $\frac{l}{r}$. When the strengths of a large number of columns are plotted against the slenderness ratio, the result is a broad belt of points through which a line can be drawn to suit any reasonable taste, or almost any formula. It is sometimes supposed that there is something erratic in the nature of column tests. For such a supposition, however, there seems to be little foundation. In the Committee's tests, the average extreme variation in each group of three members from the mean of the three, was 2.6 per cent. In the case of the Quebec Bridge tests referred to, the members are believed to have been among the largest, and certainly among the most complex, ever tested, the main section, in some cases, consisting of as many as thirty component parts. In this case, if in any, erratic results might be anticipated. Yet, in fifteen pairs tested, the average variation of a member in each pair from the mean of the two was only 1.54 per cent. In fact, it is the writer's experience, derived from several scores of tests, that compression members are rather more consistent in their behavior than large riveted tension members.

It is the writer's contention, therefore, supported as he believes by the whole body of available data, that the slenderness ratio, which in all formulas in general use is made the sole criterion for predicting the strength of columns of a given grade of material, is far from being the most important factor in the case of the great majority of heavily loaded columns. Approaching the question for the first time, and with an open mind, one would surely regard with astonishment the somewhat hair-splitting contentions in which individuals, and even committees, sometimes indulge, as to the precise function of $\frac{l}{r}$ to be used, whereas other and more important factors are ignored, except in respect to certain limiting clauses. Had equally unscientific methods been used in the calculation of tides, for instance, tide tables would have been based on the apparent diurnal motion of the moon. The consequent confusion of mariners, in Eastern waters, would hardly be greater than that of the designer who tried to correlate the strengths of various types of columns on the basis of their slenderness ratio.

It might be possible, as has been suggested, to devise different formulas for different types of column; but without much further investigation, agreement in this direction can hardly be expected. The form which it may be

thought investigation should take, will depend largely on the view entertained as to column action. The writer's experience in testing and studying the stress distribution in built-up structural members leads him to the view that, for the purpose of investigation, a column can be advantageously regarded as an aggregation of strips, each tending to yield in its own way, but restrained by mutual interaction. In solid and in thick-walled hollow sections, such restraint is practically complete, and the column acts as a unit. In such cases, if uniform material of a known quality and free from internal stress can be assumed, it should be possible to express the strength satisfactorily as a factor of $\frac{l}{r}$. In the more usual types, there will be a variation according to form and detail. If this view is correct, two corollaries seem to follow:

1.—That no method of analysis is likely to be satisfactory which assumes a linear variation of strain across the section, whatever relation between stress and strain may be assumed beyond the elastic limit, because such linear variation does not in general exist at the critical sections. Strain measurements show this to be true.

2.—That useful information regarding the laws of column action can be better obtained by an intensive study of a comparatively limited number of specimens, than by tests to destruction only, of a larger number. The latter seldom throw much light on the factors contributory to failure.

The possibilities of such intensive study are given on Fig. 14, on which is shown the stress distribution at certain sections of a column, consisting of four 2½ by 2½ by ¼-in. angles, 7 ft. 2 in. long, connected by tie-plates. The end-plates are ½ in. thick and project ½ in. beyond the angles, so as to take the load which is transmitted to the angles through the connecting rivets. The intermediate tie-plates are ¼ in. thick. The stresses at the various sections, as determined by mirror extensometers over 2-in. gauge lengths, are plotted on the cross-section as a base plane, and the resulting solid is then shown in isometric projection. The distribution of stress can thus be seen at a glance. No extensometer readings were taken on contiguous surfaces of angles or plates, so that, in such cases, the stress distribution is, to some extent, a matter of conjecture. However, in all cases, the stresses as plotted check the applied loads within 4 or 5 per cent. Section 1 is just within the first rivets nearest the ends of the angles. Most of the load remains in the plates, the angles taking only the amount transmitted by one rivet in each. At Section 2, the angles take an additional amount of load transmitted by a second rivet. The stress distribution remains far from uniform, certain fibers being in tension. At Section 5, where the angles take all the load, the stress distribution is fairly uniform, but this uniformity is disturbed again, where, as at Section 4, a tie-plate is encountered. Notwithstanding the greater sectional area at Section 4, the maximum fiber stress in the angles is about 45% greater there than at Section 5. The stress distribution at all sections remained, to a remarkable extent, the same at all loads from 20 000 to 80 000 lb.

The stress survey, of which a few of the results are here shown, was made under the writer's direction by the late Lieut. H. G. S. Delepine. Such

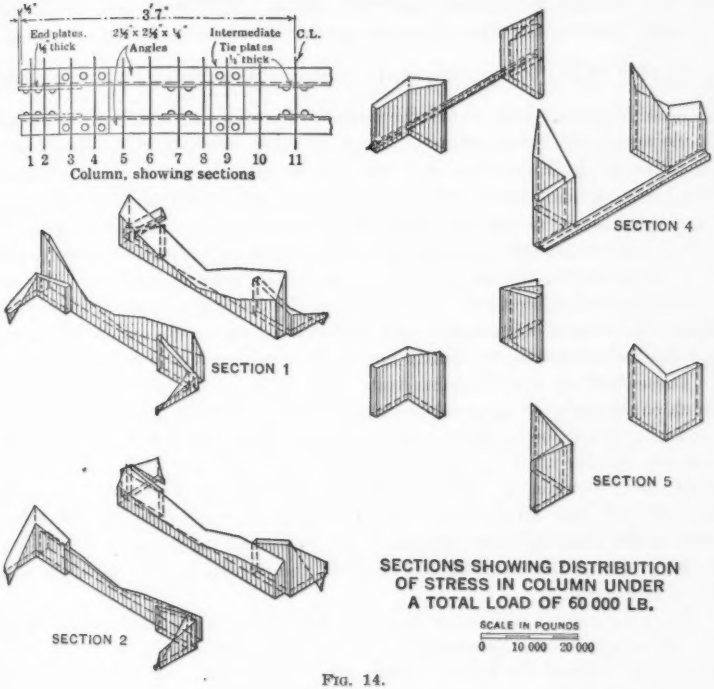

FIG. 14.

surveys are laborious; but the writer believes that only by the study of typical columns in some such manner can the Engineering Profession successfully take up the challenge which the present unsatisfactory knowledge of column action places squarely before it.

ALFRED S. NILES, JR.,* JUN. AM. SOC. C. E. (by letter).—The writer has been much interested in the discussion of the column formula. In designing aeroplane structures, it is necessary to use very slender columns and low factors of safety. On account of these two characteristics of aeroplane structural members, much research work has been done on columns of both wood and steel, the results of which are not well known to the Profession. Although the columns used in aeroplanes are small, they cover a wide range of slenderness ratios, and give interesting information on the subject of columns in general.

The most important result obtained is that the Euler formula will give the failing load for a truly centrally loaded column, provided the Euler load is less than the failing stress of the material in direct compression. Some of the most interesting tests have been made on spruce columns, in which, owing to the lack of homogeneity of wood, one might expect inconsistent results. The average crushing strength of aeroplane spruce is about 6 000 lb. per sq. in.,

* Aeronautical Structural Engr., Research Dept., McCook Field, Dayton, Ohio.

and the average modulus of elasticity about 1 800 000 lb. per sq. in. The ultimate stress by the Euler formula equals the crushing strength at values of $\frac{l}{r}$ between 50 and 60 for pin-ended columns. A series of tests was recently made at McCook Field, under the writer's direction, in which all struts with slenderness ratios of 60 or more failed at values slightly below the ultimate, according to the Euler formula. Struts with slenderness ratios of 50 and 40 failed at practically the same load as short pieces cut from the ends of the same specimens. Great care was taken to prevent eccentricities of loading, and if any measurable deflection was obtained under about two-thirds of the expected ultimate, the column was reset in the testing machine. This procedure eliminated nearly all eccentricities, whether due to lack of homogeneity of material or any other cause. The difference between the actual failing load and the Euler load was evidently due to the small eccentricity remaining.

These McCook Field column tests were made under laboratory conditions which could never be approached in engineering practice. Their value lies in proving that the lower limit of the range in which the Euler formula applies is much smaller than had previously been believed, and that the reason for using other formulas for short struts was not because the Euler formula did not hold for such struts, but because the effect of eccentricities becomes so great in the short columns that the Euler formula is no longer a safe approximation. The Euler formula does hold if the conditions are those for which it was developed.

The real problem in column design is that of making a reasonable allowance for the effect of the eccentricities which are, partly at least, unknown in magnitude. When the Euler formula gives unit stresses of less than one-half the yield point of the material, the effect of the eccentricities usually encountered is so small that it may safely be neglected as taken care of in the factor of safety. This puts the lower limit of the practical range of the Euler formula at about $\frac{l}{r} = 120$ for structural steel. As bridges have few, if any, structural members with such high slenderness ratios, the Euler formula is of little use to the bridge designer.

For columns with slenderness ratios in the range of bridge practice, allowance must be made for the effect of eccentricities, and it is most profitable to view the proposed column formulas in this light. As the eccentricity and degree of restraint of the ends of the actual column are impossible to determine accurately, it is necessary to apply empirical constants in any practical formula for columns in this range. All the formulas that are proposed for short columns have these empirical constants, even though they also have a more or less theoretical basis. This applies to the Rankine formula, and the many "eccentricity" and "secant" formulas proposed.

The column formula which should be used for practical design is the one which combines, in the greatest degree, ease of application, and agreement with test results. These advantages belong to the parabolic and straight-line formulas. The studies of A. Ostenfeld, in 1898, on the better known experimental

work, by the method of least squares, indicated that these formulas give the smaller and the Rankine and eccentricity formulas the greater mean errors.* As these formulas are not only the most easily applied, but also represent the test results the most accurately, the writer can see no reason for the attempt to use complex formulas like those proposed by Mr. Chew† and Mr. Hunley.‡ These formulas have a more theoretical basis than the parabolic formulas and appear to be more accurate, because they allow for the initial eccentricity. This appearance of accuracy, however, is illusory, as the initial eccentricity must be assumed or found empirically, and as Ostenfeld has shown, the results are not in as close agreement with the tests as those of the simpler and frankly empirical formulas.

In aeroplane design the parabolic formula is used exclusively for short columns, with excellent results, for both wood and steel members. It is easy to apply, and the constants have a definite connection with the properties of the material.

HENRY B. SEAMAN,§ M. AM. SOC. C. E. (by letter).—Several of the larger matters of general importance, having great influence in the design, such as engine loading, impact, and column formulas, have received prolonged consideration by the Special Committee on Specifications for Bridge Design and Construction, and it seems proper that these subjects should be presented more fully than is shown in the Tentative Specifications.

Engine Loading.—The subject of engine loading was considered from various standpoints. It was recognized that engine concentrations had increased far beyond the loads for which this distribution was intended originally, and that although this typical engine had simplified the calculations for design, a still further simplification was desirable, if practicable. To this end was suggested a uniform load with single concentration, and other methods, but when all things were considered, particularly the established tables and diagrams now in use, it was evident that there were no advantages over the present general practice. Furthermore, a study of the chart of engine moments and shears, as already considered by the American Railway Engineering Association,‖ showed that the typical engine distribution, even with the increased loading, gave satisfactory results as compared with the group of engines in actual service on several railroads. Whether it may yet be possible to devise a new system of loading which will conform even more closely to the engines in actual use, may be a subject for broad discussion. However, with this heavy loading, and the further provision in the Tentative Specifications for overload, it may be questioned whether it is still necessary to add the double concentration of passenger engines. This is particularly true if proper provision is made beyond 100%, for impact on spans of less than 30 ft.

Impact Formula.—The first impact formula which came to the writer's attention was presented by the late C. C. Schneider, Past-President,

* Salmon, "Columns", p. 231.
† See p. 583.
‡ See p. 568.
§ Cons. Engr., New York City.
‖ *Proceedings*, Am. Ry. Eng. Assoc., Vol. 21, p. 571.

Am. Soc. C. E., in his specification of 1887, in which $I = 0.7 + \frac{5}{L}$. This formula was introduced to simplify the design of bridges, as compared with the application of the Launhardt formula which at that time was coming into general use. Eight years later (1895), the Schneider formula was replaced by that in which $I = \frac{300}{L + 300}$, sometimes known as the "Pencoyd formula," which was introduced into the bridge specifications of the American Railway Engineering and Maintenance of Way Association of 1905, 1906, and 1910.

The subject of impact has received more consideration and prolonged discussion by the Committee than any other item of the specification. The results of the tests* made by J. E. Greiner, M. Am. Soc. C. E., on the Baltimore and Ohio Railroad Bridges, of those† made by F. E. Turneaure, M. Am. Soc. C. E., and of those‡ made more recently in England by Maj. A. Mount, R. E., were before the Committee.

The tests of the American Railway Engineering and Maintenance of Way Association, unfortunately, did not include spans less than 35 ft. in length, but the results given by Maj. Mount, shown in Fig. 15, largely supply the deficiency, although the English engine, with its inside connections, may not be directly comparable with the American engine which has its connections outside the driving wheels and, possibly, gives greater impact from unbalanced forces. In spite of this favorable consideration of the English engine, it is noticed that in Maj. Mount's results a rail bearer, composed of two halves fastened together, of 7 ft. 6 in. loaded length, gave an impact of 159% on one half and 90% on the other half, making an average of 125%; also, a loaded length of 9 ft. 8 in. gave an extreme impact of 143%, with an average of 92 per cent. Such results are rather startling to those who have made no provision beyond 100% in very short spans, but they are what should have been expected from the hammer blow of unbalanced drivers on short, rigid beams. It approaches the hypothetical condition of the "irresistible force" meeting the "immovable body". Such short spans are rarely used, and involve little extra expense, but proper provision should be made for the condition. The tendency toward a sharp increase of impact in very short spans is recognized to some extent by every impact formula that has been proposed, except the one recently adopted by the American Railway Engineering Association, in its 1920 specifications, namely, $I = \frac{300}{300 + \frac{L^2}{100}}$, which gives practically the same impact for all spans of less than 25 ft. The Committee recognized the advisability of providing for greater increase of impact on short spans—125% was incidentally mentioned for 0 span, and 100% for spans of 30 ft.

The tests show that impact for long spans—700 ft., or more—may be considered to be practically negligible. Furthermore, it is desirable to adopt a

* *Proceedings*, Am. Ry. Eng. and M. of W. Assoc., Vol. 6 (1905).
† *Proceedings*, Am. Ry. Eng. and M. of W. Assoc., Vol. 12, Pt. 3 (1911).
‡ *Engineering News-Record*, October 20th, 1921.

formula which will be applicable to spans of all lengths. There is no reason why the change from minimum impact to maximum impact should not be gradual and continuous; conditions do not reverse for short spans; but it must be remembered that the whole subject is empirical, and any formula adopted now may be modified by future experiments.

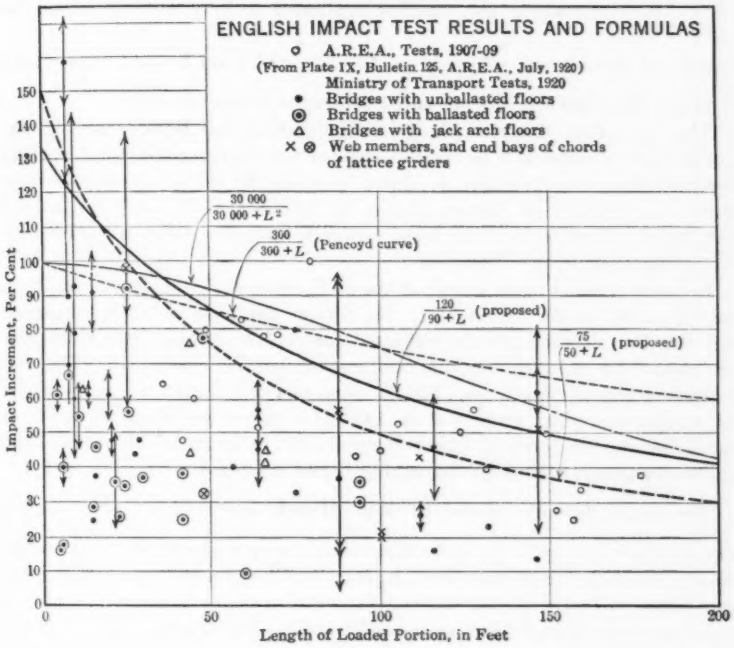

FIG. 15.

About 1905 it was the custom to use special specifications for each bridge designed, conforming to the particular conditions of span and loading. There were three or four different specifications for short spans, and another entirely different specification for long spans. There seemed to be no sharp line of demarcation between short and long spans, although it was generally assumed to be about 300 ft., at which the dead load approached or exceeded the live load. A single standard specification which would be applicable to spans of all lengths seemed to be eminently desirable. The fundamental difference in the design of short and long-span bridges was the relative action of the live load, and this should be stated in a "formula for equivalent static stress", as it was then expressed. With the use of such a formula all live load stresses might be reduced to equivalent static stresses and the allowable unit stresses modified accordingly.

At that time the impact tests of the American Railway Engineering and Maintenance of Way Association had not been made, and the only guide for

such a formula were the tests made by Mr. Greiner, previously mentioned, and the weights of bridges which had been built. The fact that impact on long spans would be negligible was already evident from the long spans erected in New York City, and has since been indicated by the tests; while, for very short spans, impact of 100%, or more, seemed to be advisable. The formula, $I = \frac{300}{L + 300}$, already in use, was not applicable to very long spans, and the formula of the quarter ellipse, $I = 125 - \frac{1}{8}\sqrt{2\,000\,L - L^2}$, was finally adopted. This formula was presented before the Society in 1912.*

The tests of the American Railway Engineering and Maintenance of Way Association, as published in its *Proceedings* for 1911, constituted a striking confirmation of this formula, as shown by Plate X† of the discussion of the writer's paper by S. W. Bowen, Assoc. M. Am. Soc. C. E. A more detailed examination of several of the tests, however, indicates further confirmation than was noticed in the discussion.

In Table 6-o the north girder of the 80-ft. span shows an impact of 122%, and the south girder shows 74%; the former again seems to be abnormal, while the latter comes near the elliptical curve. These three tests which were not plotted in the original diagram, are shown by circles (o) (Fig. 16). This curve runs from 0% for 1 000-ft. spans to 125% for 0 span, and provides for impact somewhat greater than 100% for spans less than 20 ft. It is the oldest impact formula which is applicable to spans of all lengths, and deserves consideration unless something better is offered.

The impact formula offered by Maj. Mount, namely, $I = \frac{120}{90 + L}$, gives very satisfactory results for short spans, and for spans less than 30 ft., makes proper provision of more than 100% impact; but it seems to be too high for very long spans.

In regard to impact, little more need be said. The diagram, Fig. 17, shows the striking agreement between the formula,

$$I = 125 - \frac{1}{8}\sqrt{2\,000\,L - L^2},$$

and the tests.

It has been suggested that the new A. R. E. A. impact formula is intended only for spans of 300 ft., or less. This limitation would exclude it from this specification, which covers spans of all lengths. By inspection of Fig. 16, it will be noticed that the new A. R. E. A. formula is too high even for short spans of 40 to 120 ft., where plate girders, which need no excess of strength, are used, whereas, for 120 to 300 ft., where truss spans, which need the fullest provision for loading, in anticipation of the allowable overload stress of 24 000 lb. or more, are used, the formula is deficient, notably so for spans of 210 and 300 ft. If the test, giving 22% impact for the lower chord of the 440-ft. span at Bellefontaine,‡ is plotted, it is found again to be deficient.

FIG. 17.

The selection of the proper impact formula, however, is only part of the problem of impact on bridges. The relative effect of dead load may be important, but as yet there are no tests for comparison. The effect from multiple tracks must also be considered. The provision that the load for multiple tracks shall be reduced 10%, 20%, or 30%, for two, three, or four tracks, respectively, is crude. The conditions should be susceptible of better analysis.

It is known that the impact of the tests is due mainly to the blow of the unbalanced drivers and to the synchronism of the interval of the hammer blow with that of the vibration of the span. The same synchronism from a second train is manifestly impossible. The second train would be more likely to destroy the synchronism of the first train than to augment it. Under these circumstances there should be but little additional impact from the second train. In estimating impact from the second train, it would be better, after using full impact from the first train, to use the aggregate loaded length of both tracks for the value of L, somewhat as was done in the A. R. E. A. specification of 1910. For tracks in reverse operation (as the second track in two-track bridges, and the third and fourth tracks in four-track bridges), only the uniform train load, without impact, should be used; and, in order to avoid unnecessary refinement in calculations, only full panel loads at the panel points should be considered. All bridges should be designed for possible "left-hand" train service.

In selecting an impact formula, it should be remembered that a stress of 24 000 lb. per sq. in. is provided in cases of overload, and any formula which may be adopted, therefore, should cover extreme conditions. To be able to maintain a bridge intelligently is quite as important as to construct one; in fact, engineers should always bear in mind the contingency of maintenance in bridge design.

Column Formula.—In the early days of iron bridges, the practice was to proportion columns by one of three formulas, depending on the assumed condition of the column ends, whether fixed at both ends, fixed at one end and round at the other, or round at both ends. Later, it was considered advisable to use only one formula, that for both ends round, as the end conditions of columns in a structure are uncertain, and the column may be subjected to many unforeseen conditions. For columns with round ends the formula then used was of the Rankine-Gordon type, which was considered to be so approximate, and yet so safe, that a straight-line formula might give equally satisfactory results within the limits of column length usually found in bridge design. It was a new thought, a change from the monotonous routine of years, and a recognition that engineers need not be confined to exact proportioning where unknown conditions were so prevalent. Tabulated values of r for various sections simplified its application, and the greater conveniences of the older formula—of the Rankine-Gordon type—were soon forgotten. The straight-line formula, introduced into the specifications of the American Railway Engineering and Maintenance of Way Association, of 1905, 1906, and 1910, was $p = 16\,000$ lb. $- 70\,\frac{l}{r}$.

A great number of tests of full-sized columns have been made since 1880, and these tests showed the surprising result that pin-end columns do not act as round ends, but rather as flat ends—that the bearing on the pin is apparently sufficient to fix the direction as though the column ends were flat. The tests on steel tubes also indicated that the square-end columns and the fixed-end columns gave practically the same results.

The most systematic and complete tests that have been made, except for extreme lengths, are those of the United States Bureau of Standards, for the Society's Special Committee on Steel Columns and Struts. Flat ends were used in all cases, and, in order to produce equivalent round-end tests, it is necessary to plot the results to half length.

The preference for the straight-line formula was based on its simple form, but the Special Committee on Steel Columns and Struts went one step further and almost abolished the column formula altogether. It proposed a uniform allowable stress of 12 000 lb. per sq. in. for all columns, irrespective of length, up to $\frac{l}{r} = 80$, and beyond that length the allowable stress was reduced by $100 \frac{l}{r}$, and no column was used longer than $\frac{l}{r} = 120$. Could anything be simpler? This simple formula was never actually adopted, but its influence is shown in the new straight-line formula of the American Railway Engineering Association specifications of 1920, which allows a uniform stress of 12 500 lb. per sq. in. on all columns, irrespective of length, up to $\frac{l}{r} = 50$, and beyond that length reduces the allowable stress by $50 \frac{l}{r}$. This formula is as simple as that proposed by the Special Committee on Steel Columns and Struts, except that only one-half the value of $\frac{l}{r}$, as proposed by the Committee, is deducted for long columns. Both these formulas neglect the well established rule that the maximum allowable column stress should be placed at $\frac{l}{r} = 40$, which corresponds to $\frac{l}{d} = 12$ for solid rectangular sections. The upper limit of 12 500 lb., as compared with the basis of 16 000 lb. for tension, however, seems to be a useless waste of material, and its application may involve needless expense to railroads. It will condemn many existing bridges which have been well designed under the previously accepted column formulas. It is unscientific, and is particularly objectionable in long spans, where all useless dead weight should be eliminated. The confidence in a straight-line formula appears to be wavering. The Canadian Engineering Standards Association has abandoned it altogether and adopted the "parabolic formula", $I = 12\,500 - \frac{1}{4} \frac{l^2}{r^2}$, which, although it is as purely empirical as the straight-line formula, may be used in maintenance for bridge rating. Is it not an opportune time for engineers to return to a reconsideration of the entire

subject? Each individual may formulate his own practice, but a specification should be based on scientific principles.

The Euler formula for stress due to flexure in long columns has remained unquestioned for 160 years, the only criticism being that it does not provide for the direct stress to which all columns are subjected. Engineers cannot do better than accept this as a basis for a formula for combined stresses.

The substance of the following clause is found in every bridge specification:

"Members subject to both direct and bending stresses shall be proportioned so that the combined fiber stress shall not exceed the allowable stress specified."

Long columns, at the instant of rupture, are subjected to both direct and bending stresses. The direct stress is proportional to the applied load, P. The bending stress, according to the Euler formula, is inversely proportional to $\frac{l^2}{r^2}$; thus, according to Euler:

$$P = A\,\pi^2\,E\left(\frac{r}{l}\right)^2 = c\left(\frac{r}{l}\right)^2 = \frac{c}{\frac{l^2}{r^2}} = \frac{1}{\frac{l^2}{c\,r^2}}$$

The formula for the combined stresses may then be written:

$$Y = P + P\left(\frac{l^2}{a\,r^2}\right) = P\left(1 + \frac{l^2}{a\,r^2}\right) \qquad \text{(XXI)}$$

from which may be found the theoretical fiber stress in the column for any given load, P. This is of great importance in rating the strength of old bridges in service, and is invaluable to the maintaining engineer.

From Equation (XXI) the modified Euler column formula is derived, which includes provision for direct stress:

$$P = \frac{Y}{1 + \frac{l^2}{a\,r^2}} \qquad \text{(XXII)}$$

where P is the applied load, Y is the yield point of the material at the outer fiber, and a is a constant to be found by experiment.

In long columns the yield point of the material is the ultimate strength of the column, because, at the instant of yielding, the flexure increases rapidly, and the resulting increase of the bending moment in the column will cause complete failure if the testing machine follows with full load as rapidly as the column collapses.

This formula has been in use since the early days of iron bridge design. It is applicable to columns of all lengths, and may be used in maintenance as well as in construction.

The results of tests on full-sized columns made by the U. S. Bureau of Standards for the Special Committee on Steel Columns and Struts are plotted on Fig. 18, on which also is shown the comparative value of the old and the new straightline formulas of the American Railway Engineering Association and of the modified Euler formula with relation to those tests. The coefficient, a, of the last named formula has been placed at 13 500.

For convenience in plotting the allowable stresses on columns by Equation (XXII), Table 9 of the Final Report of the Special Committee on Specifications for Bridge Design and Construction on Steel Railway Bridge Superstructure,* may be used.

The design and construction of steel bridges is still in a transition stage. The loading has been increased until it would seem that the limit had been reached, but improvements in the material are still to be expected. Steel 50% stronger than the structural steel usually specified is already in use, and there is a possibility, even a probability, that a still stronger steel may soon be offered. When this comes the formula previously mentioned will remain unchanged, except that the numerator will be increased in proportion to the increased yield point of the new material.

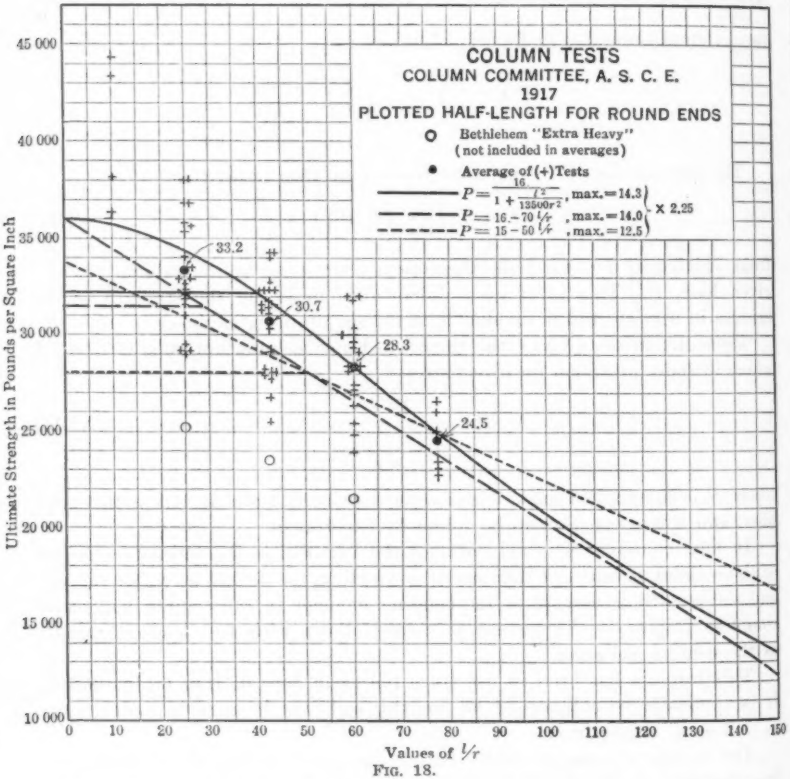

FIG. 18.

The accuracy and value of the modified Euler formula need no explanation. It is the Rankine-Gordon formula of long service. Of the two American Railway Engineering Association formulas, the old one, $P = 16\,000 - 70\,\frac{l}{r}$,

* See p. 499.

is parallel in direction to the averages of the tests, and with a slight increase of the factor of safety would practically conform to those tests; the new formula of 1920, $P = 12\,500 - 50\,\frac{l}{r}$, allows greater stresses for the longer

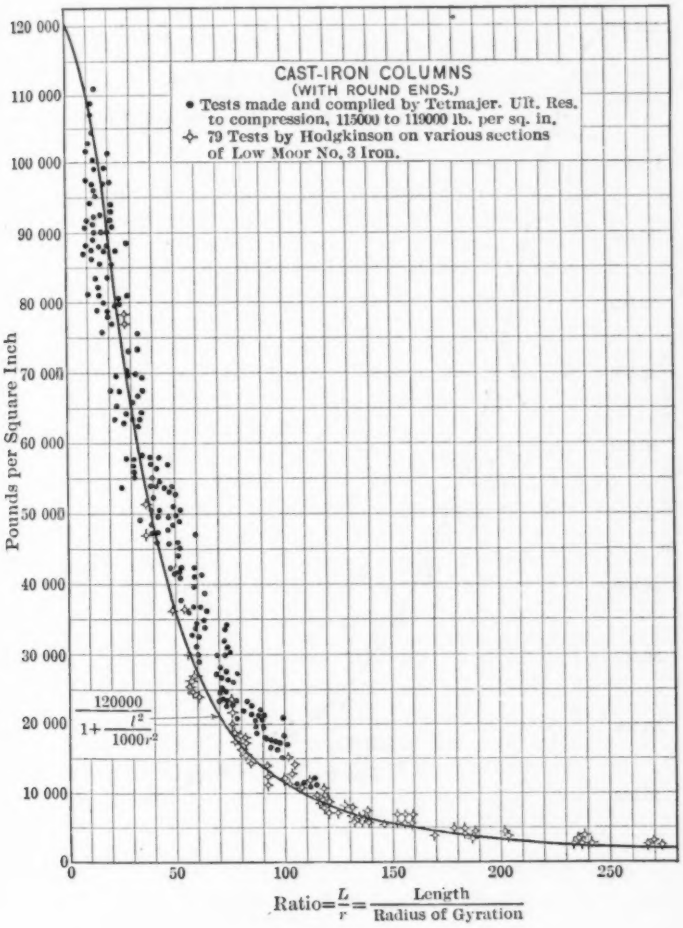

FIG. 19.

columns. Neither of these straight-line formulas can be used definitely to obtain the fiber stress to which a long column may be subjected in service. The only objection to the modified Euler formula seems to be that, for convenient use, it requires a table of values.

In Table 10 of the Final Report of the Special Committee on Specifications for Bridge Design and Construction on Steel Railway Bridge Superstructure,* is given values of the coefficient $\left(1 + \frac{l^2}{13\,500\,r^2}\right)$, Equation (XXI), for values of $\frac{l}{r}$ from 40 to 250.

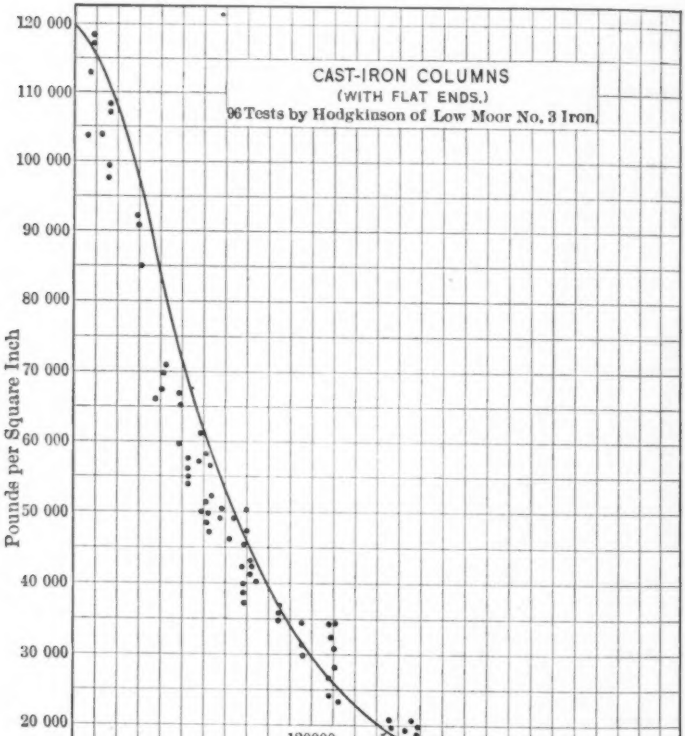

FIG. 20.

Since the early days of bridge design, the longitudinal force has been considered as due to a coefficient of friction of 20 per cent. A thorough investigation of this subject, some years ago, convinced the writer that this was an

* See p. 499.

error, and that the specification was honored more in its breach than in its observance. In his specification, previously mentioned, and for reasons then expressed, a coefficient of 10% was adopted, and this, he believes, is higher than necessary.

The strongest claim that has been offered for any practicable column formula, whether it is the straight-line or the parabola, is its agreement with the results of full sized tests. The Schwarz, the Gordon, the Rankine, or the Euler-modified, or by whatever name it may be known in its long line of endorsement, surpass any of the others in comparison with the tests, as shown in Fig. 18. The correctness of the general formula is strikingly depicted in the diagrams, Figs. 19 and 20, of tests by Tetmajer and Hodgkinson, on cast iron.* The homogeneity of the material in these tests, and the freedom from irregularities due to workmanship, make the comparison of the formula with the tests particularly instructive as illustrating the law of column flexure and failure. This formula is of a rational, if indeed not of a completely theoretical, derivation, and is the oldest and best established formula in general use. The following paragraphs seem worthy of consideration:

The fields of the American Railway Engineering Association and the American Society of Civil Engineers are distinct, as has been suggested by Mr. Guppy and others. The work of this Society is toward professional suggestion, rather than business authority. The authority, as well as the responsibility, must rest with the individual engineer.

The suggestion that a bridge should be proportioned for its ultimate load is really the crux of bridge design. It was with this in view that the writer offered a specification to the Society in 1912,† in which the loading of that time, E-40, was increased 25%, to E-50, and, at the same time, the basic unit stress of 16 000 lb. was increased 25%, to 20 000 lb., which was then considered to be the highest stress at which a bridge should be maintained. The recent adoption by the A. R. E. A. of 24 000 lb., or more, as the safe limit, has been accepted with some misgiving, but the fact that the maximum assumed loadings are seldom reached in service is probably the saving feature in the use of this high stress. Although one may prefer that a bridge be proportioned for the ultimate load, a direct specification to that effect does not seem to be practicable under the present system of railroad management. The clause for overload only partly covers this condition, and leaves waste material in the chord sections. It would be better to permit an increase of 50% in the allowable stresses specified, provided the structure, so designed, would carry a like percentage of overload.

Wind Pressure.—The structure shall be designed to resist a wind pressure, acting in either direction horizontally, of 30 lb. per sq. ft. of surfaces, as seen in elevation, the floor system, considered solid area, one truss complete, and one-half the surface of all remaining trusses (but never less than 200 lb. per lin. ft. of loaded chord, and 150 lb. per lin. ft. of unloaded chord), as well as that of a train 14 ft. high. The pressure on the train, as well as one-half the pressure on the structure, shall be considered as a moving load.

* Plotted by A. J. Malukoff, Assistant Engineer, Department of Bridges, New York City.
† *Transactions*, Am. Soc. C. E., Vol. LXXXV (1912), p. 340.

If a wind pressure of 50 lb. per sq. ft. of unloaded structure would produce greater stresses than the loading specified in Article 109, such stresses shall be used.

In calculating the stresses due to wind forces on viaduct towers, the viaduct shall be considered as loaded on the leeward track with empty cars, of weight only sufficient to prevent overturning, with a wind pressure of 500 lb. per lin. ft., acting 7 ft. above top of rail.

The requirement in some specifications that provision shall be made for a lateral force of 10% of the specified train load on one track seems very excessive. The centrifugal force of a train moving at a speed of 30 miles per hour around a 9° curve is less than 10% and no such condition could exist for a train moving on a straight track.

Unit Stresses.—In proportioning the several parts of the structure the allowable stresses shall be increased 50%, and the structure designed to carry a live load 50% greater than that specified.

Allowable Pressure on Soils.—Wherever practicable, special tests of the bearing value of the soil will be made, but in the absence of more definite information, the following pressures may be allowed:

	Kips per square foot.
Sound ledge rock	30
Hardpan, or compact gravel	16
Coarse sand, or gravel	12
Clean sand, or dry clay	8
Clay (moist)	4
Soft alluvial soil	1

On deep foundations allowance may be made for buoyancy and friction.

Allowable Pressure on Wooden Piles.—Piles shall not be placed closer than 2 ft. 6 in., centers, and will be generally designed to sustain 30 000 lb. per pile. Their supporting power, when driven, will be estimated as follows:

(*a*).—When the pile is driven to refusal and supports the load by end bearing only, without friction, allow 1 200 lb. per sq. in. of smallest cross-section, properly reduced for column length when not braced.

(*b*).—When driven to resistance by hammer blows,

$$p = \frac{2\,W\,h}{d + 1}$$

(*c*).—When driven by water jet, or in soft material,

$$p = (S\,a + R)\,L$$

in which:

p = safe load per pile, in pounds;
W = weight of hammer, in pounds;
h = height of fall of hammer at last blow, in feet;
d = penetration under last blow, in inches;
S = skin surface of pile in ground, in square feet; and
L = length of pile in ground, in feet.

Net Sections.—Net sections shall be used, in all cases, in calculating tension members, and, in deducting rivet holes they shall be taken as $\frac{1}{8}$ in.

larger than the nominal diameter of the rivet. In calculating net sections having rivets staggered, all rows shall be deducted unless arranged so that the net section along a zigzag line, taking all distances on the diagonal as 90% of their value, exceeds the corresponding net section across the plate.

It is interesting to learn, as stated by Mr. Goldmark,* that Launhardt did not take his own formula seriously and was surprised that it should have been adopted so extensively in the United States. The subject was thoroughly reviewed by the speaker, from the experiments to the final derivation of the formula, and the results presented to the Society in the form of a paper.† The conclusion reached was that the Launhardt formula was not a demonstration, and the tests themselves justified the inference that the effect of an indefinite number of applications of a load was about the same as that of the single application of a load at double this amount. This is the basis on which Cooper wrote his later specification, making the allowable live load stresses equal to one-half the allowable dead load stress. Similarly, it was seen that reversed stresses, indefinitely repeated, had the effect of the sum of these stresses if applied in one direction.

Methods of bridge design, since that time, have been entirely changed. It is recognized that a load, within the elastic limit, or yield point, may be applied an indefinite number of times without practical injury to the material from fatigue. Engineers, therefore, have sought to find the greatest stress effect of an applied train load, and, for this purpose, impact tests have been made. Whether or not those tests show the result of impact, vibration, etc., they show the greatest possible intensity from live load, and when the maximum intensity of live load is known, and the allowable stresses are kept well within the elastic limit, the assumptions provide for fatigue, and are safe.

When stresses up to 24 000 lb. per sq. in. are maintained, the limit of safety is nearly reached, considering that there are still some unknown secondary stresses. Therefore, the impact formula, so-called, should cover the most extreme conditions known. The tests which were shown, occur rarely, but they do occur, and it is just that contingency which should be met. This is the basis of present-day bridge design.

The fact that a bridge has stood the test of service does not necessarily mean that it has been economically designed or properly proportioned.

A bridge of heavy, wasteful design may show a good service record, yet another which is lighter in weight, but more rigid under traffic, may produce an equally good record in service.

LOCOMOTIVE LOADINGS FOR RAILWAY BRIDGES*

By D. B. Steinman,† M. Am. Soc. C. E.

With Discussion by Messers. C. D. Purdon, Robert C. Strachan, Victor H. Cochrane, Albert Lucius, B. A. Worthington, G. H. Gilbert, J. A. L. Waddell, Gustav Lindenthal, R. A. Caughey, J. C. Ralston, J. C. Bland, J. M. Johnson, C. S. G. Rogers, E. A. Stone, Harold C. Bird, Almon H. Fuller, Carlton T. Bishop, Clyde W. MacCornack, C. P. Disney, O. H. Ammann, Henry B. Seaman, Charles A. Mead, Herbert C. Keith, Philip George Lang, Jr., H. T. Welty, Clement C. Williams, Jonathan Jones, Glenn B. Woodruff, T. Kennard Thomson, C. R. Young, Edward Godfrey, A. F. Robinson, Lewis E. Moore, Charles B. Wing, R. O. Stewart, Henry S. Jacoby, Charles Evan Fowler, Charles F. Loweth, Ralph Modjeski, C. A. P. Turner, and D. B. Steinman.

Synopsis

For some time bridge engineers have recognized that the Cooper system of loading has ceased to provide a correct specification for the design of railway bridges, as it does not properly represent modern locomotive loadings. The specifying of different weights of Cooper engines for different lengths of span or for different members of the same span (as has been done) is, at best, a makeshift solution of the problem, and only serves to emphasize the need of a more consistent loading specification. In the successive attempts to keep pace with the continuous increase in railway loadings, the Cooper loading has been "strained beyond its elastic limit."

This paper presents a new loading system based on a study of the stress-producing effects of modern heavy locomotives.

The basic idea was to establish the maximum stresses producible at all sections of all spans by the heaviest existing locomotive loadings. The composite results showed a variation in equivalent Cooper ratings ranging from E-75 for the shorter spans to E-60 for the longer ones.

As the composite of the heaviest existing locomotive loadings is the best

* Presented at the meeting of September 6, 1922.

† Cons. Engr., New York City.

index of the directions in which the present average locomotive loadings may be expected to increase, it may fairly be taken as a standard or norm to which any new loading diagram proposed for the design of railway bridges ought to conform. The next step, therefore, was to devise a loading diagram or formula conforming as closely as practicable to this composite standard or norm. This paper offers three alternative solutions of this problem:

1.—A conventional wheel-load diagram, representing a locomotive of the Mallet type.

2.—A simplified loading diagram, consisting of a uniform load with three excess concentrations.

3.—A simple loading formula, giving directly the equivalent uniform load for any section of any span.

Each of these three alternative solutions has its distinctive advantages. The first represents the least departure from present methods, involving merely the substitution of a new and simpler wheel-load diagram for the one now in use.

The second solution offers a greatly simplified loading, which can be used expeditiously without tables or charts.

The third solution is the most scientific in principle and most convenient in application; tables, diagrams, and charts become endowed with simplicity and regularity; or, if tables and charts are not at hand, any maximum stress can be found by a simple operation on the ordinary slide-rule.

To expedite the application of the three proposed loading specifications, tables, charts, and isogonic diagrams of equivalent uniform loads are presented. Shear and moment graphs are also given, to show how closely the three proposed loadings conform to the composite standard for span lengths from 10 to 1 000 ft.

For each proposed loading system, the intensity corresponding to the composite standard is designated as Loading M-60. This loading can be increased or reduced in fixed ratios in the same manner as the Cooper system of loading. A rating chart and rating tables, included in the paper, permit quick comparison or conversion of E and M ratings for any member of any span.

Loading M-60 will give stresses for all spans very close to the maximum stresses producible by the heaviest existing locomotive loadings. It is about equivalent to Cooper's E-75 for short spans and to Cooper's E-60 for very long spans.

The adoption of Loading M-60 as a future loading specification instead of E-60 will insure that the short spans are strong enough for the heaviest locomotives and trains, without penalizing the longer spans with a 25% waste of metal.

The object of this paper is to direct attention to the inadequacy of the Cooper system to represent properly modern railway loadings; to submit, for the consideration of the Engineering Profession, three alternative forms of a new loading system based on the stress-producing effects of modern locomotives; and to secure, through discussion, a consensus of opinion as to which

of the three proposed forms should be recommended as a future loading specification.

Introduction

The Cooper system of loading was introduced into American bridge practice about 30 years ago. At that time, the heaviest loads to be provided for were properly represented by the Cooper E-40 loading, consisting of two consolidation locomotives with 40 000 lb. on each driver axle, followed by a uniform train load of 4 000 lb. per lin. ft.

Since then there has been a rapid and continuous augmentation of locomotive and train weights. To provide for this increase, the original Cooper E-40 loading was raised in successive specifications to the present values of E-60 and E-70 by applying fixed multiplying factors to the original loading diagram. This procedure could be applied indefinitely, without error, if the governing locomotive types and wheel spacings remained unchanged, and if the uniform train loads increased in the same proportion as the axle concentrations.

However, the old Consolidation locomotive has been superseded by new types of engines having different wheel groupings and weight distributions. The wheel diagrams of such modern locomotive types as the Mikado, Mallet, or Santa Fé, bear little resemblance to the Cooper engine diagram. Moreover, since the days of the E-40 loading, the axle concentrations have increased 100%, whereas the weight of train per linear foot has increased barely 50 per cent. It should be obvious, from these considerations, that a limit has been reached in the proportionate stretching of the old Cooper engine loading to make it fit modern loading conditions, and that the time has come to make a fresh start, with a system based on the existing locomotive and train loads.

Besides minor anomalies, the most serious indictment against the Cooper system is that bridges of uniform strength for present-day traffic cannot be obtained except by specifying different classes of the Cooper loading for different lengths of span and for different members of the same span. The maximum equivalent Cooper rating of the heaviest existing locomotives varies from E-75 for short spans to E-60 for long spans.

For the New York Central Lines, provision in part is made for this variation by specifying Cooper's E-70 for spans up to 200 ft. and E-65 for spans of more than 200 ft. This, however, does not provide for variations within a structure of given span.

In strengthening the Niagara Railway Arch Bridge, C. E. Fowler, M. Am. Soc. C. E., adopted E-70 for the floor system of the 550-ft. span; E-60 for the truss members of the same span; and E-70 for the truss members of the 115-ft. approach spans.

Such hybrid loading specifications, necessitated by the lack of correspondence between the Cooper system and modern train loads, have obvious disadvantages and are, at best, a makeshift solution of the problem. They serve only to emphasize the need of a new loading specification that will be more consistent with present-day traffic.

The Cooper loading does not correspond to modern locomotives, and its retention as a standard for design is unscientific. Its use produces designs that are unbalanced for present-day loadings. For instance, the Pennsylvania Railroad N-1-S locomotives are equivalent to Cooper's E-55 for some bridge members and to E-75 for others, a range of variation of 37 per cent. The Erie 2-10-2 locomotives are equivalent to Cooper's E-53 for some bridge members and to E-70 for others, a range of variation of 32 per cent. Other locomotives, compared by the writer, gave similar ranges of variation. In other words, structures designed for the arbitrary Cooper loading will not be of uniform strength for a given modern locomotive; some of the members in a span will be defective in strength in comparison with others, and some of the spans in a line will be disproportionately weak in comparison with others; and this difference in strength may amount to as much as 30 or 40 per cent.

An argument advanced for retaining the Cooper loading is that it affords a convenient standard for rating bridges; but the writer maintains that a standard that has become warped to such an extent as to yield results that fail to harmonize by 30 to 40%, has outlived its usefulness.

A new loading, in the form of a diagram, formula, or chart, should be developed for future specifications. This loading should satisfy the following requirements:

1.—It should give results that harmonize closely with the stresses producible by modern heavy locomotives.

2.—It should be heavy enough to provide for the probable future increase in loading during the desired life of the structure. Accordingly, it should be from 25 to 50% heavier than the average present loading (supposed to be represented by E-60).

3.—It should be presented in such form as will yield maximum facility of application and will discourage meaningless refinement of computation.

The foregoing considerations have prompted and guided the investigations embodied in this paper.

Composite of Heaviest Existing Locomotives

The first step toward establishing a new standard loading was to make an analysis of the stress-producing effects of the heaviest existing locomotives.

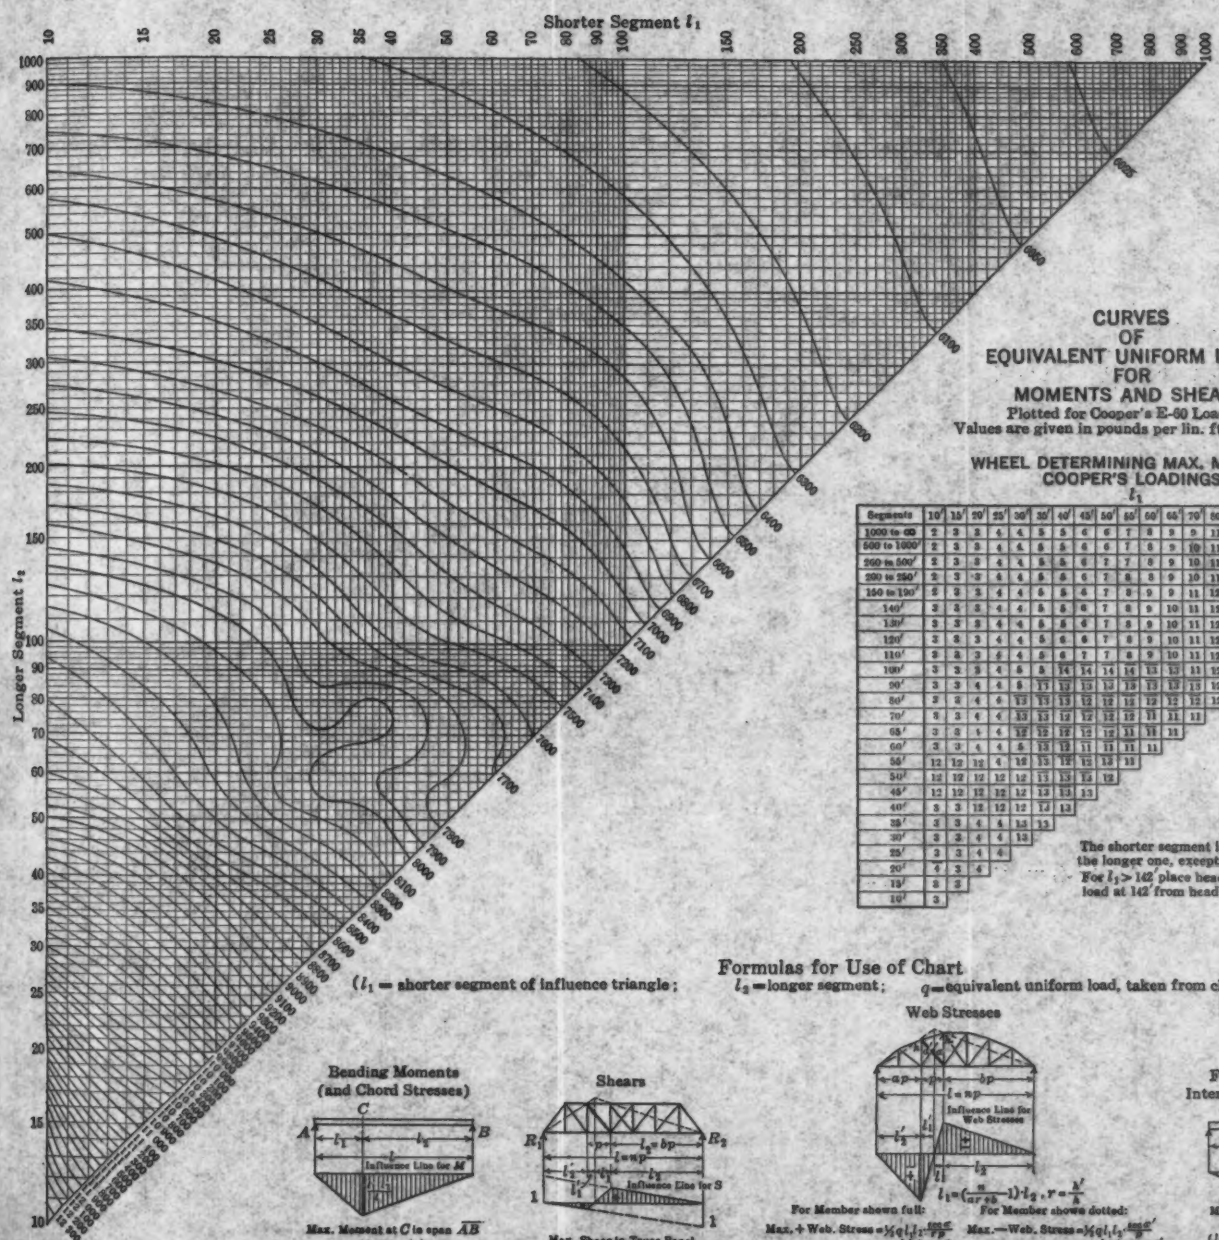
The most scientific way of studying, recording, and comparing the stress-producing characteristics of any specified loadings for all sections of all spans is on the basis of equivalent uniform loads. The equivalent uniform load for any section of any span represents the stress-producing value of a given loading, divested of all dimensional factors. Such a system of equivalent uniform loads was first published by the writer as a device for expediting the calculation of stresses for the Cooper loading. (See Plate IV.) The system is based on the principle that the equivalent uniform load for any stress depends only on the horizontal lengths, l_1 and l_2, of the two segments of the influence triangle for that stress. It is merely necessary to multiply this equivalent uniform load (taken from a table or chart) by a simple dimensional factor to obtain the maximum value of any stress.

Accordingly, the writer determined the equivalent uniform loads for the seven heaviest existing locomotives. The results are tabulated in Plate V. The locomotives included in this analysis and comparison are the following:

(1) The Erie Railroad Class P-1 (2-8-8-8-2).
(2) The Virginian Railway (2-10-10-2).
(3) Two Pennsylvania Railroad N-1-S engines (2-10-2).
(4) Two Erie engines (2-10-2).
(5) The Virginian Railway (2-8-8-2).
(6) The U. S. Standard (2-8-8-2) B.
(7) The Lake Shore and Michigan Southern Mallet (0-8-8-0).

Behind each of these locomotives is a uniform train load of 6 000 lb. per lin. ft., which fairly represents the heaviest continuous train loads. (An extra heavy coal car on the Virginian Railway weighs 5 940 lb. per ft. of track when loaded to capacity, and 6 380 lb. per ft. with 10% overload.)

The table given on Plate V covers a range of values of l_1 and l_2 extending from 10 to 1 000 ft. For each point in the table, there are recorded seven values of equivalent uniform loads corresponding, respectively, to the seven locomotives previously listed. The largest of the seven values in each block is indicated in bold-face type.



These maximum equivalent uniform loads, given in bold-face type on Plate V, represent a composite of the heaviest existing loadings. A table of these maximum values would constitute in itself an adequate loading specification to insure the safe and balanced design of all spans for the heaviest present-day locomotives.

The seven locomotives are listed in the general order of their stress-producing effects. There are, however, variations from this order; each locomotive has low points in the table, Plate V, where it is overlapped by one or more of the lighter locomotives. This fact constitutes an outstanding advantage of a composite loading, as it is free from arbitrary low points due to the individual peculiarities of a single locomotive.

It is found by inspection of the table, Plate V, that Locomotive No. 1 produces maximum stresses for all points above an indicated zigzag line corresponding approximately to a span of 150 ft. Between this line and a lower zigzag line, corresponding to a span of about 60 ft., Locomotive No. 2 produces maximum stresses. For all shorter spans, Locomotive No. 3 is the governing load. Therefore, Locomotives Nos. 1, 2, and 3 are sufficient to cover the entire field of existing locomotives as far as maximum stress-producing effect is concerned. A composite of these three engines would give stresses greater than any known loading for any section or member of any span.

In order to present in graphic form the composite stress-producing characteristics of the heaviest locomotives, the maximum values of the equivalent uniform loads were next platted on a chart, Plate VI. This diagram is of the same form as Plate IV for the Cooper loading, referred to previously. It possesses, however, striking advantages over the Cooper chart. The curves are more regular and the spacing is more even; the low points and kinks due to the idiosyncracies of the Cooper engine diagram are eliminated. The

Formulas for Use of Chart

(l_1 = shorter segment of influence triangle; l_2 = longer segment; q = equivalent uniform load, taken from chart for l_1 and l_2)

Bending Moments (and Chord Stresses)

Max. Moment at C in span $\overline{AB}$
$M = \frac{1}{2} q l_1 l_2$
(l_1 and l_2 = the segments of the span)

Shears

Max. Shear in Truss Panel
$S = \frac{1}{2} q \, l_1 l_2 \div p$
($l_1 = \frac{l_2}{n-1}$. $l_2 = bp$)

Web Stresses

$l_1 = \left(\frac{n}{ar+b} - 1\right) l_2$, $r = \frac{h'}{h}$

For Member shown full:
Max. + Web. Stress $= \frac{1}{2} q l_1 l_2 \frac{\sin\alpha}{rp}$
Max. − Web. Stress $= \frac{1}{2} q l_1 l_2 \frac{\sin\alpha}{p}$

For Member shown dotted:
Max. − Web. Stress $= \frac{1}{2} q l_1 l_2 \frac{\sin\alpha'}{p}$
Max. + Web. Stress $= \frac{1}{2} q \frac{l_1' l_2'}{l} \frac{\sin\alpha'}{p}$

Floorbeam Reactions Intermediate Pier Reactions

Max. Intermediate Reaction
$R = \frac{1}{2} q (l_1 + l_2)$
(l_1 and l_2 = the two adjoining spans.)

* Note:
In the above formula for S, the effect of wheel ① is neglected.
To correct this, subtract $20\,000\left(1 - \frac{l_2 - 1}{l_2}\right)$ from the above value of S

FOR RAILWAY BRIDGES.

smoothness of the curves is an insurance against designs becoming unbalanced by future changes in locomotive wheel diagrams.

This chart, Plate VI, does not represent any single known engine but, instead, it represents a maximum composite of all existing engines and train loads, including the heaviest types. No known loading can produce a greater stress in any member than is given by this chart. Surely this fact alone ought to commend the chart as a standard for future loading specifications.

This chart, Plate VI, may be conceived as a plat of equivalent load curves, each enveloping the corresponding curves for all existing locomotives.

The author submits this chart, Plate VI, or its tabular form, Plate V, to the Profession as a standard or norm to which any new loading diagram proposed for the design of railway bridges ought to conform. If desired, this chart alone could be incorporated in bridge specifications as a simple and adequate prescription for all railway live load stresses. Bridges designed thereby would be safe, without waste, for the heaviest loadings thus far developed.

The loading, real or imaginary, represented by this chart, Plate VI, will hereinafter be referred to as the "Composite Standard Loading", and will be designated by the class symbol, M-60.

Plate VII presents a tabulation giving for each point the equivalent uniform load for the Composite Standard Loading and, also, the respective ratios thereto of the equivalent uniform loads for the seven heaviest existing locomotives.

This table, Plate VII, is presented, primarily, to show how little the Composite Standard Loading would be changed by the omission of any one of the seven loadings entering into it. For instance, if Locomotive No. 1 were omitted, the maximum reduction of stress would be only 3.6%; if Locomotive No. 2 were eliminated, the maximum stress reduction would be only 3.9%; if Locomotive No. 3 were omitted, there would be no stress reduction, except for very short spans; if any or all of the remaining locomotives Nos. 4 to 7, inclusive) were omitted, the Composite Standard Loading would be entirely unaffected.

As the omission of any of the heaviest locomotives effects so slight a reduction in the Composite Standard Loading, it is logical to expect that the addition of any new locomotive that may be developed in the near future will produce an equally slight augmentation in the Composite Standard Loading. In other words, the Composite Standard Loading provides for probable future development in load distribution as well as for present-day loading.

The tabulation of percentages in Plate VII is also useful in comparing the stresses given by the Composite Standard Loading and those producible by any one of the heavy locomotives listed. For instance, if Locomotive No. 7 (the Lake Shore and Michigan Southern Mallet) is the heaviest locomotive on a line, and if the spans do not exceed 300 ft., the tabulation on Plate VII shows that it will be sufficient to specify 90% of the Composite Standard Loading.

If the stresses for any bridge are calculated from the chart, Plate VI, for the Composite Standard Loading, the percentages tabulated in Plate VII can then be applied, if desired, to give the exact stresses producible by any specific heavy locomotive.

The tabulated percentages in Plate VII can also be used to show the safety, under any proposed engine, of a structure designed for any other engine in the list. Other uses of this table, Plate VII, will suggest themselves to the bridge engineer.

The table on Plate VIII gives the equivalent uniform load (per track) for the Cooper E-60 loading for any section in any span and, also, the corresponding Cooper ratings for the seven heaviest locomotive loadings, in order to permit direct comparison or conversion of stresses.

Aside from the general purpose of this paper, this table, Plate VIII, is useful for determining the overloading effects of any one of the heavy locomotives on a structure designed for a given Cooper loading.

The principal object in presenting this table, Plate VIII, however, is to show the disparity between the Cooper loading and the heavy locomotives now in use. Table 1 shows the extreme variations in equivalent Cooper ratings for the seven locomotives investigated.

TABLE 1.—EQUIVALENT COOPER RATINGS OF SEVEN HEAVIEST EXISTING LOCOMOTIVE LOADINGS.

Loading.	Minimum rating.	Maximum rating.	Range of variation.
1	E-60.1	E-72.0	20%
2	E-60.0	E-73.5	23 "
3	E-54.8	E-75.0	37 "
4	E-52.7	E-69.3	32 "
5	E-56.1	E-68.2	22 "
6	E-54.7	E-66.2	21 "
7	E-52.3	E-65.0	24 "

This attempt to apply the Cooper system as a measuring standard for rating existing railway loadings reveals the difficulties that have arisen. The Cooper system and modern loadings have become incommensurable. A given modern loading cannot be expressed as a given equivalent in the Cooper system, otherwise an error of 20 to 37% will be introduced. As a measuring or rating standard for present-day traffic, the Cooper system yields results that are radically inconsistent.

LOCOMOTIVE LOADINGS
FOR RAILWAY BRIDGES.

This disproportion between the Cooper system and actual modern loadings has made it almost prohibitively difficult for the railroads to "Cooperize" their bridges. The engineer of structures of one of the prominent lines recently told the writer that it had been given up as a hopeless task. When an attempt was made to fix the Cooper rating of a bridge designed for the road's actual equipment, one Cooper rating would be obtained for the stringers, another for the floor-beams, still another for the chord members, and a different rating again for the web members.

A simple illustration of this incommensurability of the Cooper system with modern loadings is given in Fig. 1, representing the Cooper rating diagram of a 140-ft. span designed for the Pennsylvania Railroad N-1-S engines. The ratings shown are taken directly from Plate VIII.

If the bridge is intended for the modern engine, but is designed according to the Cooper loading specification, there will be a relative overstressing or waste of metal in some of the parts, amounting to 37 per cent. Such variation or discrepancy appears to the writer to be a sufficient indictment against the Cooper system as a present-day specification.

The next step was to construct a graphic chart for rating the Composite Standard Loading (M-60) in terms of the Cooper system. This chart, presented on Plate IX, was obtained by plotting the maximum E-ratings taken from the tabulation on Plate VIII.

The kinks in this chart are not due to any irregularities in the Composite Standard; they represent the peculiarities of the Cooper loading diagram. The same irregularities are found in any chart or diagram relating to the Cooper loading, whereas a chart constructed for the Composite Standard (such as Plate VI) is comparatively smooth and free from disturbing irregularities.

This chart, Plate IX, can be used as a rating chart for comparing or converting the stresses from the Cooper loading and the stresses from the Composite Loading (M-60) proposed herein as a standard. Thus, at the middle of a 40-ft. span ($l_1 = 20$, $l_2 = 20$), the proposed loading is equivalent to Cooper's E-75. At the quarter-points of a 400-ft. span ($l_1 = 100$, $l_2 = 300$), the proposed loading is equivalent to Cooper's E-63.4.

Table 2 shows the Cooper ratings of the proposed loading (M-60), for various spans, obtained from Plate IX and the corresponding table, Plate VIII.

It is also shown in Table 2 that the proposed Composite Loading (M-60) is equivalent to about Cooper's E-75 at short spans and to Cooper's E-60 at long spans. In other words, the Cooper rating of the proposed loading (M-60) gradually diminishes from E-75 to E-60 as the length of span is increased.

This variation shows that bridges of different span length in the same line will not be of uniform strength under modern loading, if they are designed for a uniform class of the Cooper loading. If designed for E-60, the shorter spans will be overstressed 25%; if designed for E-75, the longer spans will have a 25% waste of metal. Under these conditions, a single loading that will result in bridges of uniform strength for all spans and for all members in any span, should be preferred to the Cooper system. If designed

for the proposed M-60 loading, all members of all spans will be of uniform strength under modern loading conditions, and any member of any span will be strong enough, without waste, to carry the heaviest existing locomotive loads.

TABLE 2.—EQUIVALENT COOPER RATINGS OF THE PROPOSED COMPOSITE LOADING (M-60).

Having constructed, as a substitute for the Cooper system, a composite of the heaviest existing locomotives in the form of a table (Plate V) and a chart (Plate VI) of maximum equivalent uniform loads, the problem of devising a more condensed and more tangible form of representing this new loading system will be discussed. In the following pages, the writer presents three alternative solutions of this problem:

1.—A proposed engine diagram, consisting of a simple conventional system of axle concentrations, followed by a uniform train load.

2.—A simplified loading diagram, consisting of a uniform load with a floating group of three excess concentrations.

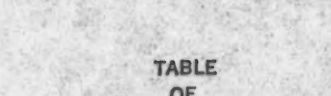
3.—A loading formula, giving directly the equivalent uniform load for maximum stress at any section of any span.

These three alternative methods of specifying the proposed loading system will be presented and discussed in turn.

PROPOSED ENGINE LOADING

The engine loading diagram devised to represent the composite of the heaviest existing locomotives is shown on Figs. 2, 3, 4, 5, 6, and 7, and Plate X.

Of necessity, a locomotive of the Mallet type was adopted. (Five of the seven heaviest locomotives, as shown on Plate V, are of the Mallet type.)



Five axles to each group of drivers were found to be necessary. (Three of the four heaviest locomotives have Decapod grouping.)

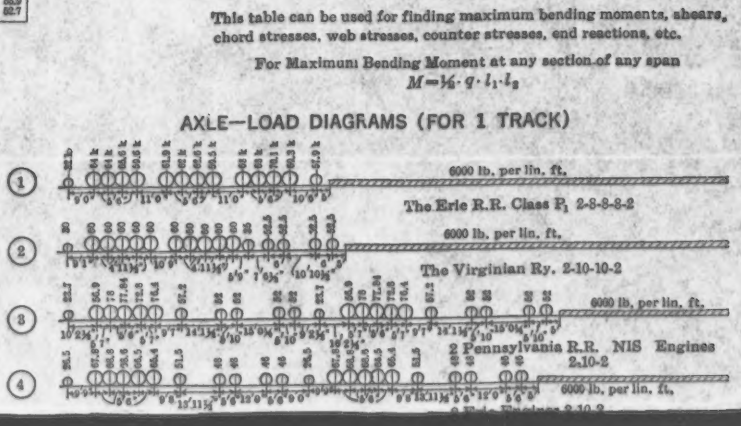
TABLE OF EQUIVALENT COOPER RATINGS FOR HEAVIEST LOCOMOTIVE LOADINGS

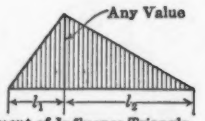


l_1 = Shorter segment of Influence Triangle
l_2 = Longer segment of Influence Triangle
q = Equivalent Uniform Load, taken from Table for the values of l_1 and l_2

This table can be used for finding maximum bending moments, shears, chord stresses, web stresses, counter stresses, end reactions, etc.

For Maximum Bending Moment at any section of any span

$$M = \tfrac{1}{8} \cdot q \cdot l_1 \cdot l_2$$



AXLE—LOAD DIAGRAMS (FOR 1 TRACK)

Longer Segment l_2

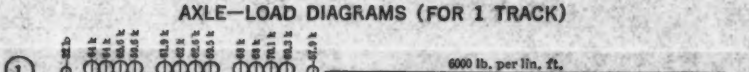
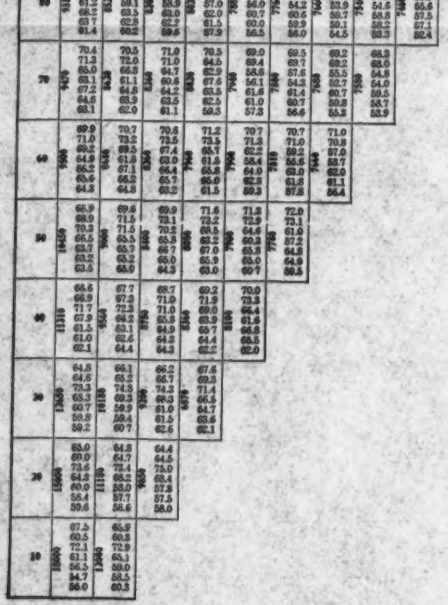
TABLE
OF
EQUIVALENT COOPER RATINGS
FOR
HEAVIEST LOCOMOTIVE LOADINGS



l_1 = Shorter segment of Influence Triangle
l_2 = Longer segment of Influence Triangle
q = Equivalent Uniform Load, taken from Table for the values of l_1 and l_2

This table can be used for finding maximum bending moments, shears, chord stresses, web stresses, counter stresses, end reactions, etc.



For Maximum Bending Moment at any section of any span

$$M = \tfrac{1}{8} \cdot q \cdot l_1 \cdot l_2$$

CHART OF COOPER RATINGS OF HEAVIEST LOCOMOTIVE LOADINGS

This chart gives the Cooper's Engine Loading equivalent to the heaviest modern locomotive loadings for any stress in any span.

This makes a total of ten driving axles, the same as in the heaviest locomotive loadings, Nos. 2, 3, and 4. (In Nos. 5, 6, and 7, there are only eight driving axles. In No. 1, there are twelve driving axles).

In order to obtain the same stresses for small spans as are produced by the heavy group of driver concentrations of Locomotive No. 3 (Pennsylvania Railroad N-1-S), it was found necessary to make one group of axle loads in the proposed engine diagram, 75 000 lb. each. Each of the axle loads in the other group were made 60 000 lb., in order to keep down the stresses for longer spans to the values produced by Locomotives Nos. 1 and 2.

The spacing of the 60 000-lb. axles was made 5 ft., as this is the closest spacing of such axles in any existing loading. The spacing of the 75 000-lb. axles was made 5½ ft., for the same reason. (In Locomotives Nos. 2, 5, 6, and 7, the 60 000-lb. axles are spaced approximately 5 ft. apart; and in Locomotives Nos. 1, 3, and 4, the heavier axles are spaced 5½ ft. apart.) The heavier group of axles was placed in the rear, following the precedent of Locomotive No. 1.

A pair of pilot wheels was added, as required by the stresses, in accordance with the precedent fixed by the six heaviest locomotives. The trailing wheels and tender, however, are considered as being absorbed in the uniform train load which follows the locomotive. As modern cars have concentrated loads exceeding those of the trailing wheels and tender, it is inconsistent refinement to represent the one by concentrations and the other by a uniform load.

The proposed engine diagram is thus reduced to a conventional 2-10-10 grouping of wheels, followed by a uniform train load of 6 000 lb. per lin. ft.

Although the engine diagram is really determined by the conditions previously set forth, the writer arrived at the same diagram by a synthetic method which closely fixed each axle load and each wheel spacing.

In constructing a chart of equivalent uniform loads, one begins with a wheel diagram and proceeds to find the corresponding equivalent uniform loads. In the present case, the problem is reversed: The equivalent uniform loads are listed for all sections of all spans in the table, Plate V, and the chart, Plate VI; it is required to construct a wheel diagram to fit these equivalent uniform loads throughout the entire range of spans and sections.

This problem is solved by starting with very short spans and determining the necessary maximum concentration. Then, by successively lengthening the span considered, successive additional axle loads are determined in magnitude and relative position, until a point is reached where the further annexing of concentrations can be dispensed with and a uniform load substituted. This, in brief, is the method that was followed by the writer, except that minor modifications of the loads and spacings were introduced in order to secure greater uniformity and simplicity.

After the engine diagram was thus determined, it was found to give results very close to those obtained with the composite of the heaviest locomotives, except for slight variations due to the rounding off of the figures adopted.

In order to facilitate the use of the proposed engine diagram and at the same time to test its conformity with the Composite Standard, the equivalent uniform loads have been computed and are presented in tabular form in Fig. 2.

l_1 = Shorter Segment of Influence Triangle.
l_2 = Longer Segment of Influence Triangle.
q = Equivalent Uniform Load taken from Chart for the values of l_1 and l_2 Values given in pounds per linear foot per track.

This table can be used for figuring the maximum stress in any member or section of any span. It gives stresses approximately equal to the maximum stresses producible by the heaviest existing locomotive loadings.

For Maximum Bending Moment at any section of any span, l_1 and l_2 = the two segments of the span.

$$M = \tfrac{1}{2} \cdot q \cdot l_1 \cdot l_2$$

For Maximum End Reaction or End Shear, $l_1 = 0$ and l_2 = the span.

$$V = \tfrac{1}{2} \cdot q \cdot l_2$$

For Maximum Shear at any section of a span, $l_1 = 0$, l_2 = the longer segment of the span and l = the span.

$$V = \tfrac{1}{2} \cdot q \cdot l_2 \cdot \frac{l_2}{l}$$

For Maximum Floorbeam Reaction or stress in Hanger, l_1 and l_2 = the adjoining panel lengths

$$R = \tfrac{1}{2} \cdot q \cdot (l_1 + l_2)$$

TABLE OF EQUIVALENT UNIFORM LOADS (PER TRACK) FOR DESIGNING RAILWAY BRIDGES

Based on Proposed Engine Loading M-60

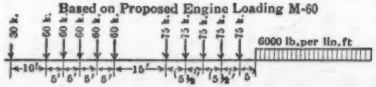

FIG. 2.

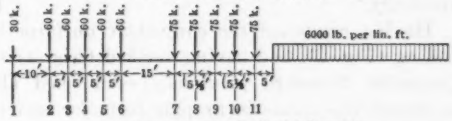
This table, Fig. 2, gives the equivalent uniform loads of the proposed engine loading (M-60) for all sections of all spans. It is found to check closely the maximum values in the similar table, Plate V, constructed for the heaviest existing locomotive loadings.

Simple methods of using this table for calculating maximum bending moments, shears, and reactions are indicated. More complete instructions for calculating maximum stresses of all kinds from equivalent uniform loads will be found on Plate IV.

Fig. 3 is a conventional tabulation of load positions giving maximum stress under the proposed engine loading. It gives the wheel to be placed at the section for any combination of values of l_1 and l_2. The equivalent uniform loads tabulated in Fig. 2 correspond to the load positions given in this table (Fig. 3).



The table (Fig. 3) shows greater regularity than the corresponding table for the Cooper loading (Plate IV). For the proposed engine loading, this table (Fig. 3) is hardly needed, as the wheel diagram is so simple and regular that load positions for maximum stress at any section can be decided by inspection. It is seldom necessary to try more than one load position for any maximum stress.

For $l_1 > 117\frac{1}{2}$ ft., place head of uniform train load at $117\frac{1}{2}$ ft. from head of span.

WHEEL DETERMINING MAXIMUM STRESS
PROPOSED ENGINE LOADING M-60

The shorter segment is ahead followed by the longer one, except wheel is overlined.

FIG. 3.

When l_1 increases beyond the value of 117.5 ft., the head of the uniform train load becomes fixed at that distance from the head of the span. Con-

sequently, for all values of l_1 exceeding 117.5 ft., the equivalent uniform load, in kips per foot, is expressible by Equation (1):

$$q = 6 + \frac{35\,320}{l_1\,(l_1 + l_2)} \quad \ldots\ldots (1)$$

For mid-span moments, $l_1 = l_2$, and Equation (1) reduces to:

$$q = 6 + \frac{17\,660}{l_2^2} \quad \ldots\ldots (2)$$

For end shears in spans of 90 ft. or more, the proposed engine loading yields an equivalent uniform load expressible by Equation (3):

$$q = 6 + \frac{606}{l_2} - \frac{17\,440}{l_2^2} \quad \ldots\ldots (3)$$

The use of Equations (1), (2), and (3), and other similar formulas, greatly simplified the computation of the equivalent uniform loads for the table on Fig 2. Moreover, these formulas represent continuous functions of l_1 and l_2 over wide areas, and, therefore, contribute to smoothness and regularity in charts or diagrams of equivalent uniform loads constructed for the proposed engine loading (Plate X and Figs. 5 and 6).

The remarkably close correspondence between the proposed engine loading (M-60) and the composite of the heaviest existing locomotives is shown in the comparative rating table, Fig. 4. This table gives, for each point, the percentage ratio of the equivalent uniform load for the proposed engine loading to the corresponding equivalent uniform load of the Composite Standard. The percentages tabulated are simply the ratios of the values in Fig. 2 to the corresponding maximum values in Plate V.

The tabulated ratios are all close to 100%; with few exceptions the variation is less than 1 per cent. At a few points, confined to very short spans, some larger variations are found, with extreme values of — 4 and + 6 per cent. These variations could have been eliminated by making one or two of the heavy axle loads in the proposed engine loading slightly more than 75 000 lb. and the adjacent axle loads correspondingly less; but the writer considered it wiser to sacrifice such hair-splitting refinement for the sake of the greater simplicity and convenience resulting from the use of five equal axle loads of 75 000 lb. The writer doubts whether any closer agreement with the Composite Standard could be obtained by the use of any other engine diagram of equal simplicity.

Having computed the equivalent uniform loads for the proposed engine loading (Fig. 2), and having verified (Fig. 4) their close agreement with the Composite Standard previously established (Plate V), the next step was to present the values in graphic form for easier application. This is done in Plate X which is a chart of equivalent uniform loads for the proposed engine loading and on which are notes that explain its use.

This chart, Plate X, agrees closely with the corresponding chart for the Composite Standard (Plate VI). The maximum variation between corresponding curves on the two charts is, except for a few unimportant points, only 1 or 2 per cent.

FIG. 4.

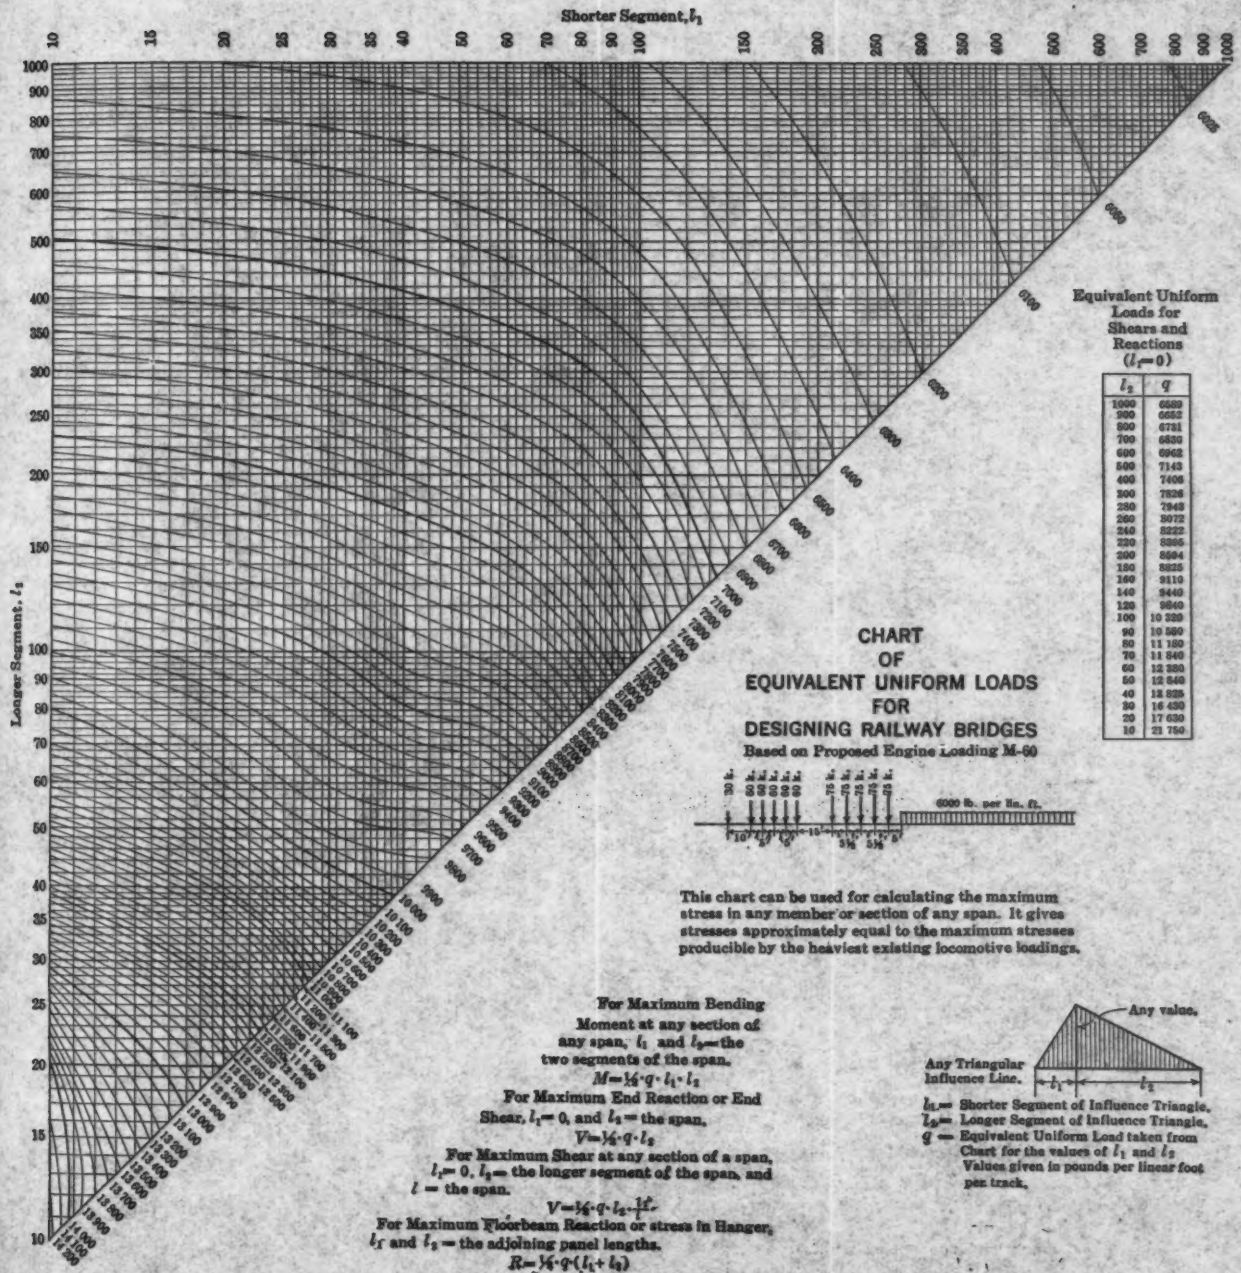
The curves on the chart (Plate X) are remarkably smooth and regular for curves derived from a loading diagram with wheel concentrations. They are free from the kinks and irregularities found in charts based on the Cooper engine diagram, which are attributable to certain minor anomalies inherent in the Cooper loading.

If the proposed engine loading (M-60) is adopted, this chart, Plate X, can be incorporated in any set of printed specifications as a "time saver" in calculating live load stresses. It gives the maximum stresses produced by M-60, which are nearly equal to the maximum stresses producible by the heaviest existing locomotive loadings.

In Fig. 5, there is presented a greatly simplified form of chart of equivalent uniform loads devised by the writer. It is in the form of an isogonic or straight-line diagram constructed by a new empirical method.

As the relation for a given engine diagram between the equivalent uniform loads, q, and the span segments, l_1 and l_2, is not expressible as a continuous function, either logarithmic or otherwise, an ordinary nomographic diagram with straight axes cannot be applied. As an alternative, the writer decided to plot the values of q in a logarithmic field, and to use the mean curve thus obtained as the q-axis. The result is shown in Fig. 5. This simple isogonic chart gives the equivalent uniform loads for the proposed engine loading (M-60). It is, of necessity, slightly approximate; but the largest error resulting from its use is only ± 4.2 per cent. This diagram possesses advantages of simplicity and ease of reproduction, which counterbalance the advantage of greater precision of the preceding chart (Plate X).

An attempt to construct a similar nomographic diagram for the Cooper loading was abandoned, as the inherent peculiarities of that loading made it impossible to obtain an acceptable result.



The small error of $\pm$ 4.2% in the isogonic chart (Fig. 5) could be still further reduced by substituting curved axes for l_1 and l_2. It requires merely a repetition of the operation by which the curved axis for q was obtained. By successive repetition of this procedure, a final isogonic chart may be obtained to give results with almost any desired degree of accuracy. The writer submits this as a suggested method for constructing an isogonic chart for any three variables between which there is a relation that is more or less regular, but which is not expressible by any continuous formula. This isogonic chart (Fig. 5) may be incorporated in specifications based on the proposed engine loading (M-60).

In Fig. 6 there is presented, in more familiar form, a graphic comparison between the different loadings under consideration, namely:

(1) The Cooper E-60 loading;
(2) The composite of the heaviest existing locomotives; and
(3) The proposed engine loading (M-60).

The stress-producing effects of these loadings are represented by graphs of equivalent uniform loads for end shears and center moments for spans of varying length.

CHART OF EQUIVALENT UNIFORM LOADS FOR DESIGNING RAILWAY BRIDGES

Based on Proposed Engine Loading M-60

This chart can be used for calculating the maximum stress in any member or section of any span. It gives stresses approximately equal to the maximum stresses producible by the heaviest existing locomotive loadings.

For Maximum Bending Moment at any section of any span, l_1 and l_2 = the two segments of the span.

$$M = \tfrac{1}{2} \cdot q \cdot l_1 \cdot l_2$$

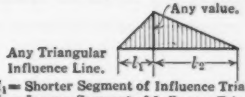
For Maximum End Reaction or End Shear, $l_1 = 0$, and l_2 = the span.

$$V = \tfrac{1}{2} \cdot q \cdot l_2$$

For Maximum Shear at any section of a span, $l_1 = 0$, l_2 = the longer segment of the span, and l = the span.

$$V = \tfrac{1}{2} \cdot q \cdot l_2 \cdot \tfrac{1}{l}$$

For Maximum Floorbeam Reaction or stress in Hanger, l_1 and l_2 = the adjoining panel lengths.



$$R = \tfrac{1}{2} \cdot q \cdot (l_1 + l_2)$$

l_1 = Shorter Segment of Influence Triangle.
l_2 = Longer Segment of Influence Triangle.
q = Equivalent Uniform Load taken from Chart for the values of l_1 and l_2 Values given in pounds per linear foot per track.

Equivalent Uniform Loads for Shears and Reactions

q	6589	6652	6731	6830	6962	7143	7406	7826	7943	8072	8222	8395	8594	8825	9110	9440	9840	10 320	10 580	11 180	11 840	12 380	12 840	13 825	16 430	17 630	21 750

This Chart can be used for figuring the maximum stress in any member or section of any span. It gives stresses approximately equal to the maximum stresses producible by the heaviest existing locomotive loadings.

l_1 = Shorter Segment of Influence Triangle.
l_2 = Longer Segment of Influence Triangle.
q = Equivalent Uniform Load taken from Chart for the values of l_1 and l_2
Values given in pounds per foot per track.

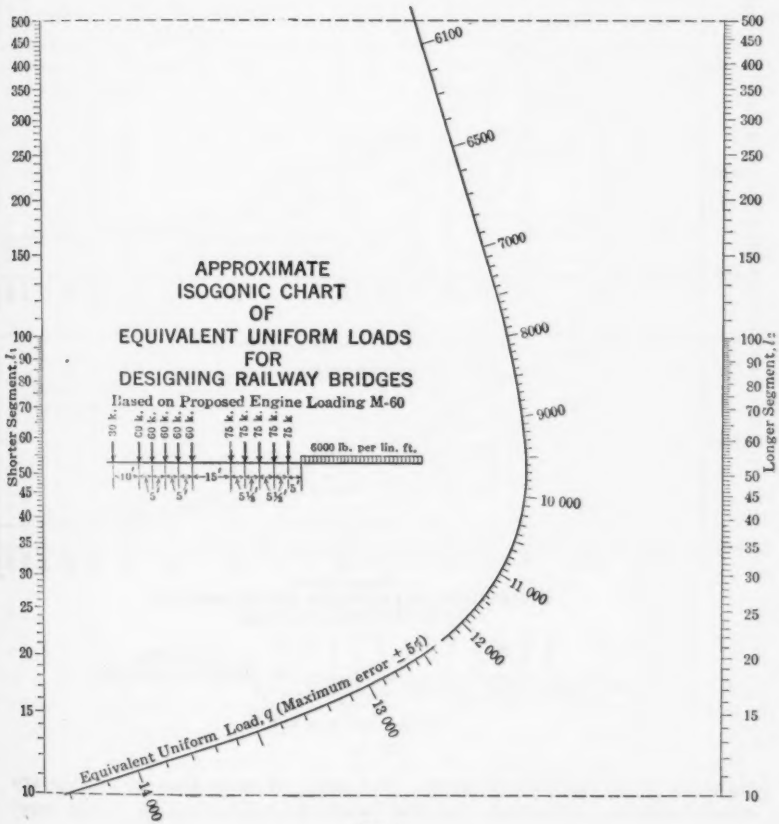

FIG. 5.

For both shears and moments, the Composite Standard is about 25% heavier than Cooper's E-60 at short spans and gradually approaches coincidence with the latter at very long spans. If Cooper's E-75 is substituted, it will cause an excess of 25% at long spans.

For end shears, there is the discrepancy of a few per cent., previously mentioned, between the Composite Standard and the proposed engine loading (M-60) at short spans. Except for spans of less than 24 ft., the

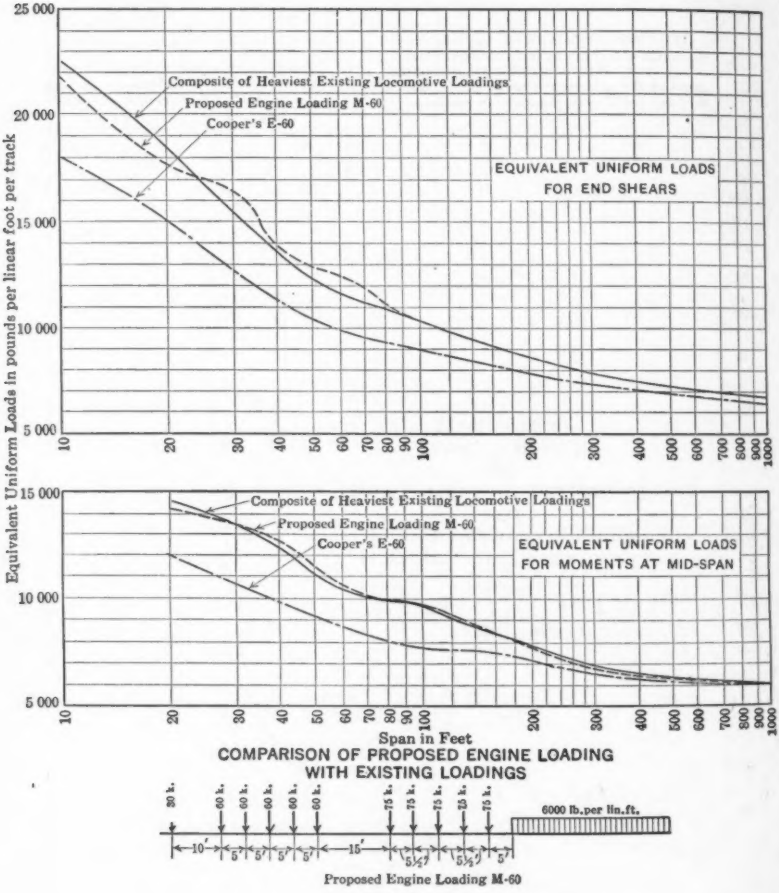

FIG. 6.

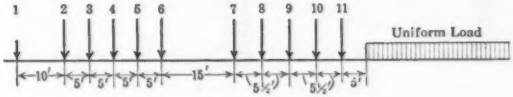
variation is on the side of safety. For spans of more than 90 ft., the two curves coincide, indicating that the proposed engine loading is the exact equivalent of the Composite Standard in this range.

In the graphs for center moments, there is a remarkable agreement between the proposed engine loading (M-60) and the Composite Standard. The



two curves follow each other throughout, with maximum variations of only 1 or 2%, except for one point having a difference of 2.9 per cent.

This agreement between the two curves is as close as could reasonably be demanded. Closer agreement cannot be secured without sacrificing the simplicity and uniformity of the proposed wheel-load diagram. The variation is so small that the proposed engine loading (M-60) may safely be accepted as a close equivalent of the composite of the heaviest existing locomotives.

The tabulation in Fig. 7 shows how the proposed engine loading can be diminished or augmented in fixed ratios to form different classes, in the same manner as the Cooper system of engines.

After conference with other engineers, the writer has decided to designate the proposed engine loading, previously derived, as equivalent to the heaviest modern locomotives, by the class symbol, M-60. The letter, M, stands for "Modern", "Motive Power", or "Mallet". The class number is made 60 to symbolize, in the conventional manner, the weights of the first group of driver axles and the weight of the uniform train load. An additional reason for the designation, 60, was to simplify the conversion to different classes.

PROPOSED ENGINE LOADING SYSTEM FOR DESIGN OF RAILWAY BRIDGES

Loads per Track

M-10 = 5	10	10	10	10	10	12.5	12.5	12.5	12.5	12.5	1000 lb. per lin. ft.
M-40 = 20	40	40	40	40	40	50	50	50	50	50	4000
M-50 = 25	50	50	50	50	50	62.5	62.5	62.5	62.5	62.5	5000
M-60 = 30	60	60	60	60	60	75	75	75	75	75	6000
M-70 = 35	70	70	70	70	70	87.5	87.5	87.5	87.5	87.5	7000
M-80 = 40	80	80	80	80	80	100	100	100	100	100	8000
M-90 = 45	90	90	90	90	90	112.5	112.5	112.5	112.5	112.5	9000

Loading M-60 will give stresses for all spans very close to the maximum stresses producible by the heaviest existing locomotive loadings. It is approximately equivalent to Cooper's E-75 for short spans and to Cooper's E-60 for long spans

FIG. 7.

Reducing the proposed engine loading to Class M-10, as a basic unit, there is a pilot axle of 5 k., five driver axles of 10 k., and five driver axles of 12.5 k., followed by a uniform load of 1 000 lb. per lin. ft. This simple loading is all that need be given in a specification. By multiplying this unit loading, M-10, by 4, 5, 6, 7, 8, or 9, the loadings, M-40, M-50, M-60, M-70, M-80, and M-90 are obtained.

Loading M-60 will give stresses for all spans very close to the maximum stresses producible by the heaviest existing locomotive loadings. To allow

for probable future increase in weight of traffic, the writer would recommend that Loading M-50 be specified in present-day specifications with a provision for an excess loading of 50%; or, what amounts to the same thing, Loading M-60 may be specified with a provision for an excess loading of 25 per cent.

l_1 = Shorter Segment of Influence Triangle.
l_2 = Longer Segment of Influence Triangle.
q = Equivalent Uniform Load taken from Chart for the values of l_1 and l_2. Values given in pounds per linear foot per track.

This table can be used for figuring the maximum stress in any member or section of any span. It gives stresses approximately equal to the maximum stresses producible by the heaviest existing locomotive loadings.

For Maximum Bending Moment at any section of any span, l_1 and l_2 = the two segments of the span.

$$M = \tfrac{1}{2} \cdot q \cdot l_1 \cdot l_2$$

For Maximum End Reaction or End Shear, $l_1 = 0$ and l_2 = the span.

$$V = \tfrac{1}{2} \cdot q \cdot l_2$$

For Maximum Shear at any section of a span, $l_1 = 0$. l_2 = the longer segment of the span and l = the span.

$$V = \tfrac{1}{2} \cdot q \cdot l_2 \cdot \frac{l_2}{l}$$

For Maximum Floorbeam Reaction or stress in Hanger, l_1 and l_2 = the adjoining panel lengths

$$R = \tfrac{1}{2} \cdot q \cdot (l_1 + l_2)$$

TABLE OF EQUIVALENT UNIFORM LOADS (PER TRACK) FOR DESIGNING RAILWAY BRIDGES

Based on Proposed Simplified Loading M-60

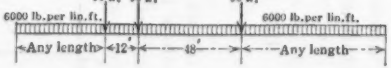

FIG. 8.

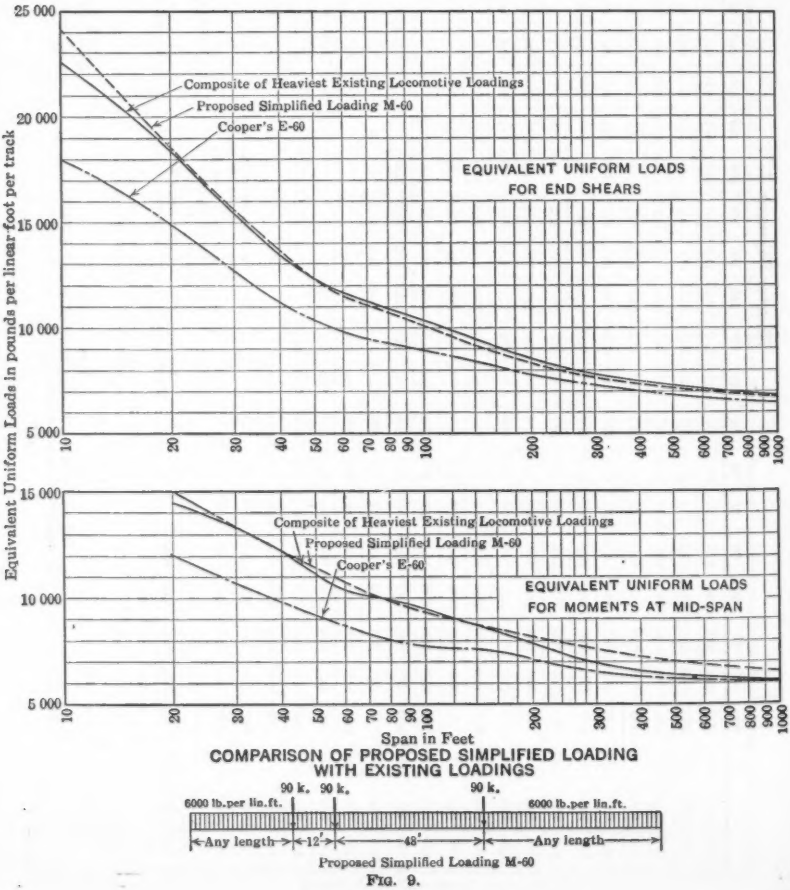
It will be observed, from Table 3, that the Cooper equivalent of M-50 diminishes from E-64 at short spans to E-50 at very long spans.

A reverse rating or conversion table is presented in Table 4 which gives the M-ratings of the Cooper E-60 loading for various spans.

According to Table 4, the M-equivalent of Cooper's E-60 ranges between M-47 at short spans and M-60 at long spans; but it is fairly well represented by M-50 for all spans below 100 ft.

Proposed Simplified Loading

As an alternative for the proposed engine diagram to represent the composite of the heaviest existing locomotives, the writer has devised an equivalent simplified loading which has certain advantages and may be preferred by some engineers.



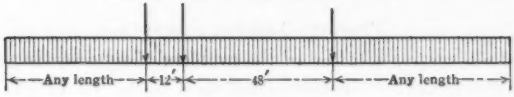


FIG. 9.

This proposed simplified loading (Figs. 8, 9, and 10) consists of a continuous uniform load of 6 000 lb. per lin. ft., on which is superimposed a floating group of excess concentrations. These concentrations, determined after a number of trials, consist of three 90 000-lb. loads spaced 12 ft. and 48 ft. apart, respectively.

The use of a simplified loading of this form greatly facilitates the computation of maximum stresses. Any stress is calculated by simply considering the uniform load and then adding the independent contribution of the group of concentrations. The latter contribution is quickly found; there are only three concentrations and they are easily placed and easily calculated. For stringer and floor-beam spans, only the first two concentrations enter.

To expedite still further the calculation of maximum stresses for this proposed simplified loading, and to permit direct comparison with the composite of the heaviest existing locomotives, a table of equivalent uniform loads is presented in Fig. 8. The computation of this table consumed only a small fraction of the time required for the similar table of equivalent uniform loads (Fig. 2) for the proposed engine loading, indicating the greater convenience and despatch of stress computations with the simplified loading.

PROPOSED SIMPLIFIED LOADING
UNIFORM LOAD WITH EXCESS CONCENTRATIONS
FOR DESIGN OF RAILWAY BRIDGES

Loads per Track

M-10	15	15	15	1000 lb. per lin. ft.

M-80	120	120	120	8000
M-90	135	135	135	9000

Loading M-60 will give stresses for all spans very close to the maximum stresses producible by the heaviest existing locomotive loadings. It is approximately equivalent to Cooper's E-75 for short spans and to Cooper's E-60 for long spans

FIG. 10.

Comparison of the values in this table (Fig. 8) with the equivalent uniform loads for the composite of the heaviest locomotives (Plate V) shows a sufficient agreement for all practical purposes. With the exception of some end shear values, where there is a maximum deficiency of 2.7%, the variations are on the side of safety. In other words, the proposed simplified loading will yield stresses equal to or somewhat greater than the heaviest existing locomotive loadings. Closer agreement could have been secured by varying the con-

centrated loads, but it was deemed preferable to keep the three concentrations equal for the sake of simplicity.

Moment and shear graphs comparing the simplified loading with existing loadings are presented in Fig. 9. The shear graph closely follows the curve for the Composite Standard, except for a variation of a few per cent. (on the safe side) at very short spans. The moment graph also follows the Composite Standard curve up to a span of about 200 ft., where it begins to deviate (on the safe side) with a maximum excess of about 10% at 500-ft. span.

It may be noted that the moment and shear graphs for the simplified loading are smoother than the corresponding curves for either the Composite Standard or the proposed engine loading.

To provide for different loading classes, similar to the different classes in the Cooper system, the proposed simplified loading can also be expressed in multiples of a smaller unit loading, as indicated in Fig. 10.

The simplified loading described, approximately equivalent to the heaviest modern locomotives, is called M-60. Accordingly, Loading M-10 consists of a uniform load of 1 000 lb. per lin. ft. with three excess concentrations of 15 k. each. Classes M-40, M-50, M-60, M-70, etc., are simply the corresponding multiples of Loading M-10.

For present-day specifications, as previously suggested, the writer would recommend Loading M-50 with provision for an increase of 50% or, what is equivalent, Loading M-60 with provision for an increase of 25 per cent.

Proposed Loading Formula

As a third alternative solution of the problem of representing the composite of the heaviest locomotives in more condensed form, the writer offers a loading formula which gives directly the equivalent uniform load at any section of any span.

In the opinion of other engineers besides the writer, this is an ideal solution of the problem, as a formula possesses many advantages over an engine diagram:

1.—It yields results of singular smoothness and regularity, unattainable with any diagram of wheel concentrations. The minor irregularities in stress variation due to unavoidable peculiarities in any concrete engine diagram are eliminated.

2.—It is a "time saver," as it yields maximum stresses directly without the labor of shifting a wheel-load diagram and calculating the contributions of individual concentrations.

3.—It facilitates the construction of tables, stress diagrams, and charts, and yields diagrams of greater simplicity, smoothness, and accuracy.

4.—It is more easily remembered than a wheel-load diagram, and saves repeated reference to the specifications.

5.—It makes the designer independent of reference books, as the ordinary slide-rule takes the place of all tables, diagrams, and charts.

6.—It is more flexible than a wheel-load diagram, being more easily modified to adjust it to any desired change in variation of equivalent loads with length of span.

7.—It is more scientific than an arbitrary loading diagram.

The formula devised by the writer to represent the maximum equivalent uniform loads of the heaviest existing engines, as tabulated on Plate V and plotted on Plate VI, is presented in Figs. 11, 12, 13, and 14, and Plates XI and XII, inclusive. It is as follows:

$$q = 5\,000 + 60\,000 \frac{\sqrt{l_2}}{l_1 + l_2} \quad \ldots\ldots(4)$$

in which,

l_1 = the shorter segment of the influence triangle for any stress;
l_2 = the longer segment of the influence triangle; and
q = the corresponding equivalent uniform load for maximum stress.

To obtain Equation (4), the writer platted the composite values of q for varying spans on logarithmic cross-section paper. He soon found that the graphs representing q — 5 000 were closely approximated by straight lines having a slope corresponding to the convenient exponent, $\frac{1}{2}$. The graph for end shears yielded Equation (5), as follows:

$$q = 5\,000 + \frac{60\,000}{\sqrt{\text{span}}} \quad \ldots\ldots(5)$$

and the graph for center moments yielded Equation (6):

$$q = 5\,000 + \frac{30\,000}{\sqrt{\frac{1}{2}\text{ span}}} \quad \ldots\ldots(6)$$

The resemblance between Equations (5) and (6) at once suggested that they could be considered as two special cases of one general formula, namely,

$$q = 5\,000 + \frac{r \times 60\,000}{\sqrt{r \times \text{span}}} \quad \ldots\ldots(7)$$

in which r = the position ratio in the span of the section considered. For end shears, the section is at the end of the span, consequently, $r = 1$, yielding Equation (5). For center moments, the section is at mid-span, consequently, $r = \frac{1}{2}$, yielding Equation (6). For maximum bending moment or chord stresses at the quarter-point of a span, $r = \frac{3}{4}$, and Equation (7) would yield:

$$q = 5\,000 + \frac{45\,000}{\sqrt{\frac{3}{4}\text{ span}}} \quad \ldots\ldots(8)$$

For maximum shear at the quarter-points of a span, the equivalent uniform load is the same as for end shear in a span only three-quarters as long, consequently,

$$q = 5\,000 + \frac{60\,000}{\sqrt{\frac{3}{4}\text{ span}}} \quad \ldots\ldots(9)$$

These examples show how simple the actual application of the formula becomes.

In order to facilitate the application of Equation (7) to finding maximum stresses of all kinds, it is expressed in more general form by introducing the symbols, l_1 and l_2, for the two segments of the loaded length of span. It then becomes:

$$q = 5\,000 + 60\,000 \frac{\sqrt{l_2}}{l_1 + l_2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (10)$$

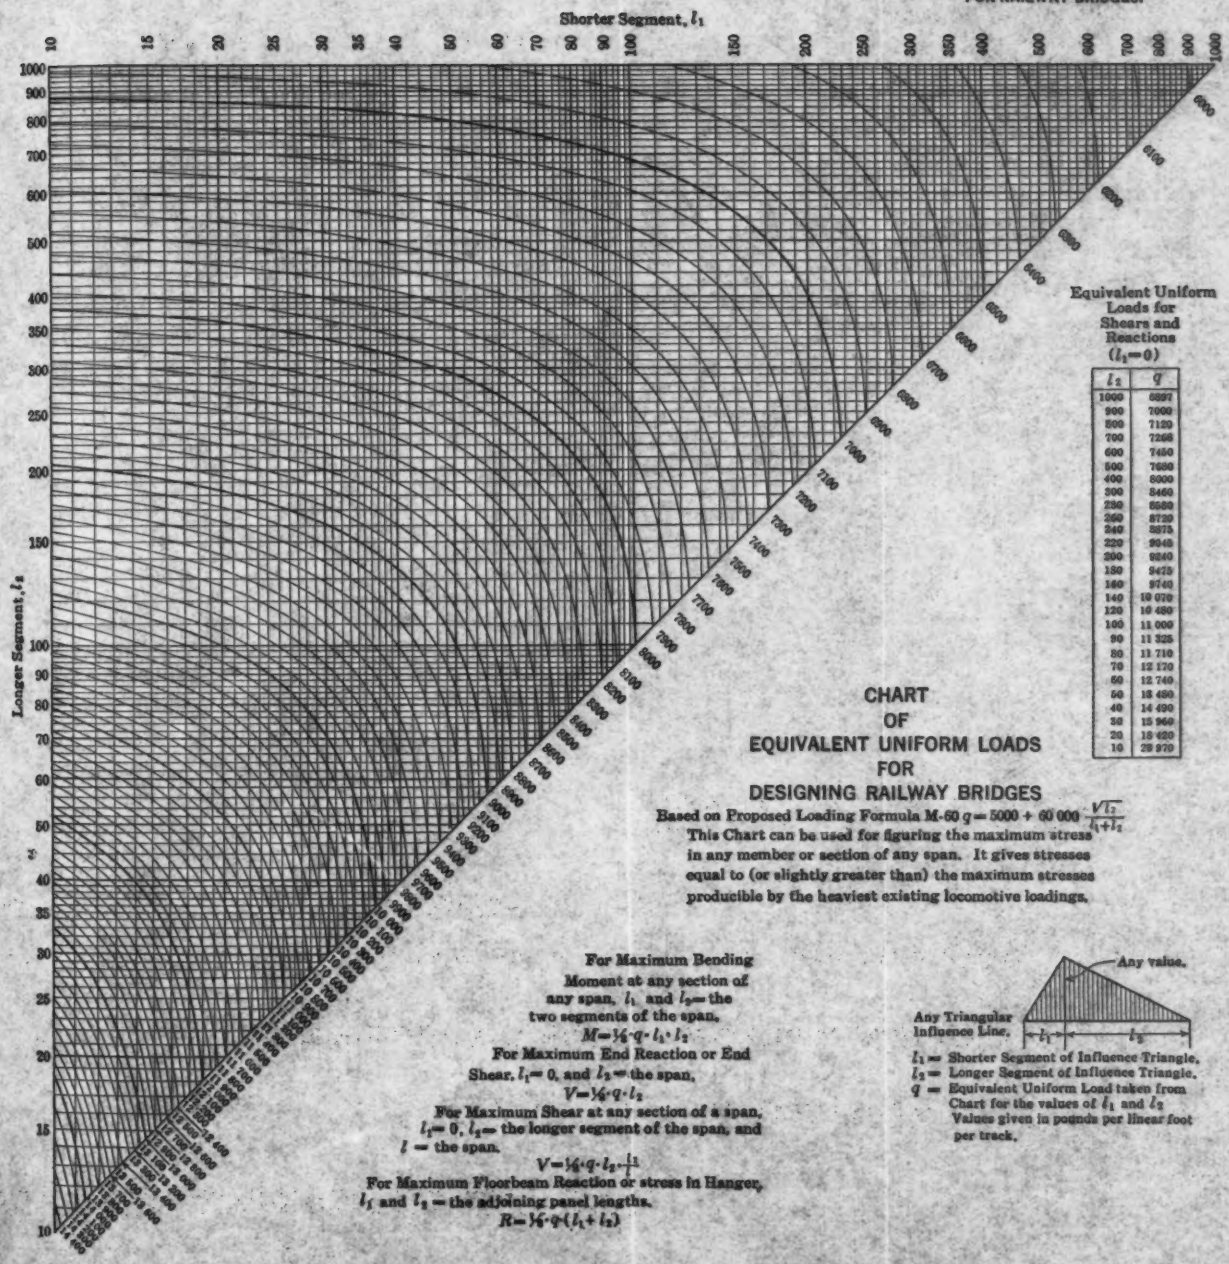
which is the proposed loading formula.

Empirical formulas for equivalent uniform loads have been proposed in recent years, but they were deficient in one respect, namely, they expressed the equivalent uniform load as a function merely of the span without regard to the position of the member or section in the span.

The proposed formula, notwithstanding its simplicity, makes full provision for the necessary variation of equivalent uniform load for different sections or members in the same span. For instance, in the case of a 100-ft. span, the proposed loading formula yields values of q varying from 9 240 for bending moments or flange stresses at mid-span, to 11 000 for flange stresses near the ends of the span; and from 11 000 for end shears to 13 480 for shears near mid-span; a total range of variation of 46 per cent. This variation corresponds to the actual stress-producing effects of locomotive loadings, and the reproduction of this appropriate variation of equivalent uniform loads within a given span is an important advantage of the proposed loading formula.

The possibility of fairly close representation of the equivalent uniform loads for all sections of all spans by a single formula is a point of superiority of the proposed Composite Standard over the Cooper engine loading.

The equivalent uniform loads yielded directly by the proposed loading formula for various sections of various spans are tabulated on Fig. 11. This tabulation can be incorporated in printed specifications to expedite the calculation of stresses based on the formula.



The tabulated values on Fig. 11 agree fairly well with those in the corresponding tables (Fig. 2 and Fig. 8) for the other proposed loadings. Except for only 4 or 5 values out of 405 in the table (Fig. 11), the values are on the safe side in comparison with the composite of the heaviest locomotives (Plate V). Closer agreement could have been secured by adopting a formula with an odd decimal exponent; but it appeared preferable to keep the simpler expression, although it varied somewhat (on the side of safety) from the exact values desired.

Platting the values tabulated on Fig. 11, one obtains for the proposed loading formula, a chart of equivalent uniform loads, Plate XI. This chart, although yielding nearly the same values throughout as the similar preceding charts, Plates VI and X, possesses a marked advantage in the perfect smoothness and systematic regularity of its curves. As irregularities in a chart may be regarded as weak spots in the stress-producing effects of the corresponding loading specification, the ideal regularity of the curves in Plate XI constitutes a strong argument in favor of the proposed loading formula.

General instructions for the use of the chart are given on Plate XI. More complete directions for finding maximum stresses of all kinds are given on the similar chart for the Cooper loading, Plate IV.

A much simpler chart for the proposed loading formula is an isogonic diagram presented in Plate XII. The equation between q, l_1, and l_2, is of such

CHART OF EQUIVALENT UNIFORM LOADS FOR DESIGNING RAILWAY BRIDGES

Based on Proposed Loading Formula M-60 $q = 5000 + 60\,000 \frac{\sqrt{l_2}}{l_1 + l_2}$

This Chart can be used for figuring the maximum stress in any member or section of any span. It gives stresses equal to (or slightly greater than) the maximum stresses producible by the heaviest existing locomotive loadings.

For Maximum Bending Moment at any section of any span, l_1 and l_2 = the two segments of the span,

$$M = \tfrac{1}{8} \cdot q \cdot l_1 \cdot l_2$$

For Maximum End Reaction or End Shear, $l_1 = 0$, and l_2 = the span,

$$V = \tfrac{1}{2} \cdot q \cdot l_2$$

For Maximum Shear at any section of a span, $l_1 = 0$, l_2 = the longer segment of the span, and l = the span.

$$V = \tfrac{1}{2} \cdot q \cdot l_2 \cdot \frac{l_2}{l}$$

For Maximum Floorbeam Reaction or stress in Hanger, l_1 and l_2 = the adjoining panel lengths.

$$R = \tfrac{1}{2} \cdot q \cdot (l_1 + l_2)$$

l_1 = Shorter Segment of Influence Triangle.
l_2 = Longer Segment of Influence Triangle.
q = Equivalent Uniform Load taken from Chart for the values of l_1 and l_2
Values given in pounds per linear foot per track.

FIG. 11.

form as to permit a perfect nomographic solution of conventional form. A straight-line chart of this form, yielding exact values for the equivalent uniform loads, cannot be constructed for any loading specification consisting of a diagram of axle concentrations. The isogonic diagram, Plate XII, is submitted merely as a suggestion. By varying the arrangement and scales of the three straight-line axes, other engineers can easily construct variations of this chart that may better suit their individual preference.

In the construction of the diagram, the values of span $(l_1 + l_2)$ and longer segment (l_2) are platted on ordinary logarithmic scales. The q-axis is a similar logarithmic scale, except that the constant, 5 000, has been added to each numbering.

One drawback of this isogonic chart, Plate XII, is the relatively small scale of the q-axis, which limits the precision attainable. The chart of curves, Plate XI, gives greater precision with equal, if not greater, expedition.

To overcome objections arising from the crowding of the graduations near one end of the q-axis in the exact nomographic diagram Plate XII, there is presented in Fig. 12 an isogonic chart of a more convenient form constructed for the same loading. This is an empirical and, therefore, slightly approximate, isogonic diagram of the type devised by the writer and previously described in connection with Fig. 5.

The smoothness and simplicity of this approximate nomographic chart (Fig. 12) for the proposed loading formula are unattainable with any other loading specification considered in this paper. The accuracy attainable is sufficient for most practical purposes, the greatest errors being less than ± 4 or 5 per cent. This chart can be easily reproduced and incorporated in any printed specifications based on the proposed loading formula. For the Cooper loading, a chart of this form is practically out of the question.

Moment and shear graphs are presented in Fig. 13 for the purpose of comparing the proposed loading formula with existing loadings. These graphs show that the proposed loading formula is a much closer and safer representation of the composite of the heaviest locomotives than the present Cooper loading.

For end shears, the graph for the proposed loading formula follows fairly close to the Composite Standard, with all variations on the side of safety.

For mid-span moments, the graph for the proposed loading formula is again a fairly close approximation to the Composite Standard, with a deficiency of only a few per cent. at short spans and a small variation on the safe side at long spans.

For stresses at intermediate sections of a span, the variations from the Composite Standard will be intermediate between the corresponding variations for end shears and center moments.

The moment and shear graphs for the proposed loading formula shown in Fig. 13 are obviously smoother curves than are attainable with any loading specification consisting of a diagram of wheel concentrations.

Fig. 14 shows how a system of loading classes similar to the Cooper system can be constructed from the proposed loading formula. Designating the

intensity of loading corresponding to the formula as derived from the Composite Standard as M-60, the unit base, or M-10 loading, becomes:

$$q = 833 + 10\,000\,\frac{\sqrt{l_2}}{l_1 + l_2} \qquad (11)$$

COMPARISON OF PROPOSED LOADING FORMULA WITH EXISTING LOADINGS

Proposed Loading Formula M-60

$q = 5000 + 60\,000\,\frac{\sqrt{l_2}}{l_1 + l_2}$

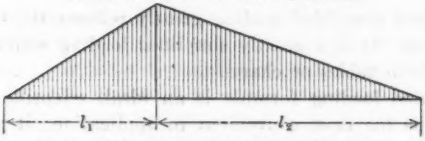
l_1 = Shorter Segment of Influence Triangle,
l_2 = Longer Segment of Influence Triangle,
q = Equivalent Uniform Load

FIG. 13.

Multiplying this loading by the constants 4, 5, 6, etc., the successive classes, M-40, M-50, M-60, etc., are obtained.

Loading M-60 will give stresses for all spans equal to or slightly greater than the maximum stresses producible by the heaviest existing locomotives. To provide for a future increase of 25%, it is suggested that specifications recommend Loading M-50 with provision in the design for a 50% overload, or Loading M-60 with a provision for a 25% overload.

Conclusion



After showing the inadequacy of the Cooper system to represent modern loading conditions properly, the writer has constructed a Composite Standard covering the stress-producing effects of the heaviest existing locomotives and has been devised three alternative forms of specification conforming to this Composite Standard.

The advantages over the Cooper system of any loading specification based on the Composite Standard are:

1.—The proposed specification makes it possible to design bridges strong enough in all their parts, without waste, for the heaviest existing locomotive loadings, without requiring separate computations for each loading.

2.—The proposed specification gives bridges of uniform strength in all

M-10	$q = 833 + 10\,000$	$\frac{\sqrt{l_1 l_2}}{l_1 + l_2}$
M-40	$q = 3333 + 40\,000$	$\frac{\sqrt{l_1 l_2}}{l_1 + l_2}$
M-50	$q = 4166 + 50\,000$	$\frac{\sqrt{l_1 l_2}}{l_1 + l_2}$
M-60	$q = 5000 + 60\,000$	$\frac{\sqrt{l_1 l_2}}{l_1 + l_2}$
M-70	$q = 5833 + 70\,000$	$\frac{\sqrt{l_1 l_2}}{l_1 + l_2}$
M-80	$q = 6666 + 80\,000$	$\frac{\sqrt{l_1 l_2}}{l_1 + l_2}$
M-90	$q = 7500 + 90\,000$	$\frac{\sqrt{l_1 l_2}}{l_1 + l_2}$

Loading M-60 will give stresses for all spans very close to the maximum stresses producible by the heaviest existing locomotive loadings. It is approximately equivalent to Cooper's E-75 for short spans and to Cooper's E-60 for long spans

Fig. 14.

their parts for present and prospective future loadings, without requiring different load ratings for different members in a span.

3.—The proposed specification gives designs of uniform strength for bridges of all spans under present and prospective future loadings, without requiring different load ratings for different lengths of span.

4.—The proposed specification, being based on the heaviest modern locomotives and train loads, better represents the future development to be expected in loadings than a specification based on the engines and train loads of thirty years ago.

In addition, the proposed specification, in the three forms presented by the writer, offers advantages over the Cooper loading in simplicity, regularity, ease of computation, and greater facility of diagrammatic representation.

Of the three alternative forms developed in this paper for the proposed new specification, each has distinctive features to recommend it:

1.—The proposed loading diagram represents the smallest departure from present methods, involving merely the substitution of a new and simpler wheel-load diagram for the one now in use. It will best meet the requirements of engineers who prefer a concrete picture of a locomotive as a loading specification. Furthermore, it affords the closest agreement throughout the entire range of spans with the composite of the heaviest existing locomotives.

2.—The proposed simplified loading greatly reduces the time and labor of calculating stresses. It is a greatly simplified loading which can be handled expeditiously without tables or charts.

3.—The proposed loading formula is an ideal, scientific form of loading specification. It is the most convenient in application; it yields tables, diagrams, and charts of unequalled simplicity and regularity; or, if tables and charts are not at hand, any maximum stress can be found by a simple operation on the ordinary slide-rule. It is a "short-cut" specification, virtually prescribing stresses rather than loads.

If this paper only serves to direct attention to the inadequacy of existing loading specifications, and to indicate the general lines of attack in determining a new specification to be adopted, the writer will feel repaid for the labor expended.

DISCUSSION

C. D. PURDON,* M. AM. SOC. C. E. (by letter).—The author appears to assume that, at some time, all railroads will have to provide for such engines as the enormous ones described in the paper. Although it is true that cars of any kind may be encountered on any railroad, they may be pulled by small engines, and bridges should provide for these as a minimum. Such engines as those described in the paper are for exceptional places, very heavy tonnage, and heavy grades, and are not likely to be found on roads which do not have such grades and business. The load of heavy cars, expressed as weight per foot, does not express their effect on bridges. For instance, the car of the Norfolk and Western Railroad Company, of 5 346 lb. per ft., has a maximum effect in shear of a little more than E-48 and in moment, of E-47. A gondola of the Pennsylvania System, of 3 980 lb. per ft., overloaded 10%, has a maximum effect of E-44.5 when in solid trains, but if alternated with 80 000-lb. cars fully loaded, it has an effect of E-31 on spans of 60 ft. and more.

The typical engine described by the author does not resemble an engine and is only a load per foot and his M-loading might as well be used. This would require a purchaser to turn the engine he desires into M-loading. Although the tractive power of M is not given—as it generally runs about 22% of weight on drivers—an M-loading, on a line with maximum grades of 0.5%, would haul more cars than could be handled.

In preparing the 1920 specifications, the Iron and Steel Structures Committee of the American Railway Engineering Association canvassed carefully all kinds of loading and finally decided on the Cooper series as being the most suitable. The specification is for spans of 300 ft. and less; for longer spans, the same loading "per foot" could be used; and, for long spans, the floor and some members are designed by the Cooper loading, but the trusses are on a "per foot" basis.

The author states that his M-loading provides for future increase. The A.R.E.A. loading also allows for a future increase by using a unit stress of 16 000 lb., after adding impact. This has been criticized by some engineers. Why not use the actual safe stress of, say, 20 000 or 22 000 lb. per sq. in.? If the M-loading allows for increase, consider it with a unit stress of 20 000 lb., which is the same as adding 25% to the Cooper loading. Then, taking Fig. 6 and adding 25% to the Cooper E-60 brings a curve practically the same as M-60 up to 80 ft., after which it is a little above that loading. Few railroad companies in the West would care to build their trestle bridges for such a loading.

Some years ago, the writer made a comparison of engines of different kinds, with the Cooper loading, using E-55 as a base. Through the courtesy of the Baldwin Locomotive Works, many diagrams were obtained. These diagrams were reduced to an equivalent load of 55 000 lb. on each driving axle, and either the shear or the moment was plotted, the highest value being used, but as the following load is only an assumption, the supposed bridge was a deck

* Cons. Engr., St. L. S. W. Ry., St. Louis, Mo.

girder up to 120 ft. This diagram* indicates that the engines of the Santa Fé type would make a fairly regular curve up to 120 ft., as they probably would not be "double-headed". A following load of about 7 000 lb. (which is about the weight per foot of the engine itself) might be used. With regard to the Cooper loading not representing the actual, consider the effect of a Consolidation engine (double-headed), rated at about E-42, on a 200-ft. span originally built for the Cooper A, which is approximately E-25. The Cooper rating will range from E-37.58 to E-39.59 for the lower chord members, and from E-37.65 to E-45.61 for the web members.

The Santa Fé type seems to be a favorite; Record 88 of the Baldwin Locomotive Works, which is dated 1917, states that between 1903 and 1906, the Atchison, Topeka and Santa Fé Railway Company had bought 160 locomotives and had since bought 32 more; that the Chicago, St. Paul, Minneapolis and Omaha Railway Company had bought 2 engines; the Texas and Pacific Railway Company, 26; the Duluth, Missabe and Northern Railroad, 6; the Chicago Great Western, 7; the Union Pacific, 27; the Chicago, Burlington and Quincy, 66; the Lehigh Valley, 76; the Southern, 55; the St. Louis, San Francisco, 60; the Bessemer and Lake Erie, 20; the Baltimore and Ohio, 30; and the Erie, 20; and, in June, 1922, 50 locomotives were on their way to the Southern Pacific.

The average weight of these locomotives (all super-heater) is 548 745 lb.; on drivers, 294 482 lb.; tractive power, 72 973 lb. (equal to 24.78%); length, 81 ft. 9 in.; weight per foot, 6 596 lb.; and weight per pound of tractive power, 7.52. Comparing these with nine Consolidated locomotives, taken at random, we have: Weight, 336 155 lb.; on drivers, 191 711 lb.; tractive power, 46 008 lb. (equal to 24%); length, 68 ft.; weight per foot, 4 938 lb.; and weight per pound of tractive power, 7.36. Six ten-wheelers gave 22% tractive power, with an average weight per pound of tractive power of 10.22. This indicates that the Santa Fé type carries no more load in proportion than a Consolidated engine, not superheated, and less than a ten-wheeler.

ROBERT C. STRACHAN,† M. AM. SOC. C. E. (by letter).—The author has performed a valuable work by his analysis of the bases underlying much present practice in specifying train loads, and by making evident some of the inconsistencies involved in attempting to adapt to present-day conditions an ancient generalization, which, although excellent in its day, has outlived its usefulness. His constructive suggestions merit the careful consideration of the bridge engineer.

A reading of the paper compels one to realize that, although stresses and sections are computed to the "twentieth part of one poor scruple", rivets numbered and placed with the minutest attention to primary, secondary, or even tertiary, stress, and impact coefficients determined with the utmost refinement, the completed structure may be far from good, if not designed for the loads actually to be carried at once, or reasonably to be expected during its life.

The author's recommendations as to a new specification of the amount and distribution of train loads, based on his study of many pertinent data, are

* Published in *Engineering News*, of October 23, 1913, but without the Erie Triplex.
† New York City.

advanced in three forms; the second and third of these forms are derived from the first, and are shown to possess advantages due to possible simplifications in mathematical processes. These advantages are of undoubted weight; but the second and third forms are, as it were, "implicit functions" of the first, reflecting all its possible imperfections, and tending to remove the nub of the argument a step farther in any discussion of the merits of the author's suggestions.

In drawing any specification, it would seem preferable to state the fundamental requirements, rather than the results of conclusions drawn therefrom by methods which themselves may be open to argument. Accordingly, confining the discussion to the proposed conventional axle-load diagram (Fig. 7), the author's determination of M-60 after careful study of the stress-producing effects of the heaviest existing locomotives, and his subsequent building up of a series of M-diagrams bearing simple ratios to M-60, in the manner of the Cooper loading, is an important step in the direction of introducing a scientific and modern standard load system for the economical design of railroad bridges and for the rating or comparison of their carrying capacities; a system of which the need is admittedly great in consequence of the changes in locomotive construction which have taken place since the Cooper system of loading was devised.

Although professional opinions may differ as to the degree of approximation to the truth attained in the use of the proposed conventional system, its adoption would tend toward augmented economy and toward the elimination of many unprofitable complications inseparable from the use of an obsolete load specification.

Although it is the writer's opinion that neither the second nor the third form of the author's recommendations should appear as a load specification, both of them, with the accompanying diagrams, will commend themselves as "short-cuts" for use under suitable circumstances.

VICTOR H. COCHRANE,* M. AM. SOC. C. E. (by letter).—The author's tables and diagrams clearly show that, in the Cooper series, there is a lack of balance between the locomotive axle concentrations and the uniform train load. The maximum axle load is ten times as great as the train load per linear foot, whereas in the case of the heaviest loadings now in use this ratio is about 13. For some locomotive loadings the discrepancy is not so great; for instance, the last three loadings of the group of seven presented by the author are fairly well represented by the Cooper E-60 loading. However, if these same locomotives were followed by a lighter uniform loading, such as the 210 000-lb. cars assumed by a committee of the American Railway Engineering Association† in its study of the moments and shears produced by modern locomotives and cars, the Cooper loading would again be out of balance. It seems desirable, therefore, to make the axle loads heavier in proportion to the uniform train load than is done in the Cooper series.

* Cons. Engr. (Cochrane, Willrich and Johnson), Tulsa, Okla.
† *Proceedings*, Am. Ry. Eng. Assoc., Vol. 21.

Modern locomotives differ so greatly in the arrangement and spacing of axle loads that no single type can be found to represent all of them, unless it is a more or less conventional system, such as the author's first alternative loading. A composite loading derived from a number of different types of heavy locomotives will undoubtedly be more nearly representative of future loadings than any single loading series, and, consequently, will make more adequate provisions for future developments in locomotive design.

Of the three alternative loadings proposed, the writer prefers the loading formula, as it is by far the simplest and most direct. There seem to be two principal objections to its use: First, that it does not give a graphic picture or diagram of the axle concentrations and uniform load to which it corresponds; and, second, that it is not in close enough agreement with the composite loading. These objections are outweighed by the advantages which are well stated by the author.

In regard to the first objection, which relates to the lack of a loading diagram, there is no reason why an approximate equivalent loading, such as the author's first alternative, should not be used in connection with the formula to show approximately the loads provided for.

Concerning the second objection, that relating to the differences between the formula loading and the composite loading, it may be pointed out that, inasmuch as different locomotives in use give widely different results, and as there is no way of knowing exactly the future trend of locomotive design, these discrepancies are of minor consequence.

However, if desirable to do so, it is practicable to devise a formula which will agree much more nearly with the composite loading than that of the author. Such a formula might not be quite as simple in appearance as that of the author, but it would be practically as convenient to use. The following is suggested as an alternative to the author's formula, using the same notation:

$$q = 4\,400 + \frac{50\,000}{\sqrt{l_1 + l_2}} - 600 - \frac{l_2 - l_1}{l_2 + 3\,l_1}\left(\begin{matrix}\text{plus } 3\,000 - 60\,l_2, \text{ for} \\ \text{shears when } l_2 < 50\end{matrix}\right).$$

This formula reduces to:

$$q = 5\,000 + \frac{50\,000}{\sqrt{l_2}} \text{ (plus } 3\,000 - 60\,l_2, \text{ for } l_2 < 50), \text{ for shears;}$$

$$q = 4\,600 + \frac{50\,000}{\sqrt{L}}, \text{ for quarter-span moments;}$$

$$q = 4\,400 + \frac{50\,000}{\sqrt{L}}, \text{ for mid-span moments.}$$

This formula agrees with the composite loading practically as closely as the first alternative loading. Table 5 shows the values obtained by the author's formula and by that of the writer, also the percentages of error based on the maximum values of the composite loading. It will be noted that for moments this formula gives a series of curves parallel to the end shear curve. The Cooper loading is different in this respect, as will be seen.

The Cooper E-60 loading can be represented by a similar formula with practically the same degree of accuracy that is shown in Table 5 for the M-60 loading. The general formula is:

$$q = 5\,000 + \frac{30\,000 + 10\,000\,\dfrac{l_2 - l_1}{l_2 + 3\,l_1}}{\sqrt{l_1 + l_2}},$$

which reduces to:

$$q = 5\,000 + \frac{40\,000}{\sqrt{l_2}}, \text{ for shears;}$$

$$q = 5\,000 + \frac{33\,300}{\sqrt{L}}, \text{ for quarter-span moments;}$$

$$q = 5\,000 + \frac{30\,000}{\sqrt{L}}, \text{ for mid-span moments.}$$

The degree of accuracy of this formula may be determined by comparison with Plate IV.

The author's formula becomes:

$$q = 5\,000 + \frac{60\,000}{\sqrt{l_2}}, \text{ for shears;}$$

$$q = 5\,000 + \frac{52\,000}{\sqrt{L}}, \text{ for quarter-span moments;}$$

$$q = 5\,000 + \frac{42\,400}{\sqrt{L}}, \text{ for mid-span moments.}$$

It seems likely that any system of loading that may be adopted, can be represented closely enough for practical purposes by a general formula similar to that just mentioned.

The author's suggestion in regard to the use of a formula (or charts and tables corresponding thereto), is a valuable one, and is worthy of adoption.

ALBERT LUCIUS,* M. AM. SOC. C. E. (by letter).—The writer believes the tendency in future bridge loadings will not be toward increased driver axle loads, as the economical limit of rail service is against it, but that the number of drivers will be increased where more traction unit is demanded. He also believes that when the electrification of railroads takes place, as sooner or later it will, new motor diagrams will be developed, aiming at a more uniform and equal maximum of motor axle and car axle loads, with a view to reducing maintenance-of-way costs of roadbed and structures.

Referring to the author's request for an expression of preference concerning several alternate propositions for railway bridge loadings in specifications, the writer's preference is as follows: Specify the maximum local axle loads and spacing, the heaviest typical locomotive diagram, and the train load per foot of track.

This expression of preference is without prejudice to the value and correctness of the author's carefully prepared paper and his conclusions and recom-

* Cons. Engr., New York City.

mendations as contained therein. The writer begs to express his full appreciation of the labor involved and of the service which the author has rendered to the Profession by its publication.

B. A. WORTHINGTON,* ESQ. (by letter).—Relative to the author's suggestion of a wheel loading for locomotives to be used in bridge design to displace the Cooper loading, there is no doubt but that the Cooper loading diagram was scientifically developed, and that at the time of its adoption it was the best and most efficient specification for the locomotives in use. However, the present type of heavy locomotive has outgrown the Cooper loading diagram and the writer thinks the point made by Mr. Steinman is well taken, namely, that the Cooper loading diagram will have to be modified materially if the stresses in railway bridges are to be uniform and no waste in material is to occur.

The importance of making this change is brought out by the author's calculations showing a variation of practically 30 to 40% in stresses, and as a result of his analysis, he suggests three proposed engine loadings.

The writer has studied this matter carefully with the Chief Engineer of the Cincinnati, Indianapolis and Western Railroad Company, H. F. Passel, M. Am. Soc. C. E., and it seems that the first suggestion, namely, "the proposed engine loading (M-60)," would be the most desirable, for the reasons set forth by the author, that this diagram represents the least departure from present practice in bridge design, and that it more nearly represents graphically actual conditions.

G. H. GILBERT,† ESQ. (by letter).—The author is correct in the claim that the design of railway bridges for E-60 loading does not properly provide for the loading of modern types of engines and the actual axle loads used with such engines. A few years ago, the writer was requested to recommend a bridge loading for new specifications. Although no final recommendations were ever made, some preliminary data were developed, particularly as to the weight of engines in service on the railroads of the United States. The tentative conclusion was that modern locomotive loadings were properly protected by a typical Santa Fé engine with driver axle loads of 65 000 lb., assuming a 20-ft. driver wheel-base and a total wheel-base of 70 ft. of the engine and tender.

The author recommends a loading equivalent to E-75 for short bridges followed, for the longer structures, with a uniform train load of 6 000 lb. per lin. ft. Such a loading is equal to or greater than that of any locomotive now in service. It may be questioned whether railroad executives will approve of such a heavy loading. The Profession and railroad bridge engineers in general, can recommend only such heavy loadings as are in use to any appreciable extent, and such as are indicated by the trend of manufacture, as shown by locomotives built.

As indicated previously, it is considered that an E-60 loading does not properly protect the drivers of Santa Fé engines, nor properly care for the heavy

* Pres., The C. I. & W. R. R., Indianapolis, Ind.
† Engr. of Bridges, Southern Ry. System, Lines West, Cincinnati, Ohio.

axle loads now being used. Attempts to emphasize such facts are usually met with the claim that the heavy driver axle loads are exceptional and required by the use of special experimental engines or engines designed for special and particular operating requirements, together with the further claim that the Santa Fé type is not necessarily a permanent type and no great number of such engines are in service.

In Table 6, statistics are given, compiled largely from the *Railway Age Gazette,* showing locomotives for use in the United States, as ordered for each year from 1911 to 1921, inclusive. Table 7 gives the variation in weight of the several types of heavy engines, together with the approximate average loading per driver axle. These data would indicate that most of the heavy engines in service have driver axle loads between 55 000 and 65 000 lb.

Table 8 contains data, compiled from special articles, showing heavy driver axle loads. It will be noted that an average driver axle load exceeding 60 000 lb. is common, that this loading is as high as 67 000 lb. for three different

orders, and that, in one case, it is as high as 72 400 lb. The last loading and the highest single axle loading of 78 000 lb., are for a single engine.

The recent tendency of locomotive design is toward the increasing use of the Mikado and the Santa Fé types of engine, with little change as regards the use of Mallet engines. The heavy Mountain type of passenger engine is more in demand. This type is virtually an adaptation of the Mikado type for passenger service. On account of the extended wheel-base, its loading, from the standpoint of bridge design, may be neglected, as it will be lighter than the Mikado engine. During the last four years, the data presented show that 15% of the engines ordered are of the Santa Fé type and that 60% are strictly heavy power, with driver axle loads of from 55 000 to 65 000 lb.

It appears obvious to the writer that, in selecting a proper bridge loading, the Santa Fé type can no more be ignored than any other type of engine. If that fact is once granted, it follows that many short spans and the floor systems of the through spans designed for E-60 loading will, at unit stresses, only take the Santa Fé engines when the driver axle loads are reduced to

about 53 000 or 54 000 lb. The tendency of driver axle loading is the reverse. A railroad using 60 000-lb. axle loads, with the old type of engines, such as the Consolidation, is forced by the need of tractive power to use 63 000 to 66 000 lb. for axle loads of its Mikado and Santa Fé engines.

In considering a broad matter like bridge building, affecting the development of railroads for the next 15 or 20 years, it is well to keep close to fundamentals. The types and weights which have developed within the last 10 years are due to an ever-increasing demand for tractive power. For passenger engines and freight engines of the Mikado type, there is the added demand of speed. The Santa Fé and Mallet types are probably restricted to use with drag freights, and the Mikado engine is the most popular freight engine. The use of a trailer develops the full value of the weight on the four drivers, so that in the future any increased tractive power must be obtained either by increasing the weights on the drivers, or by changing the type of engine. From some standpoints, the change to a Santa Fé or Mallet type is objectionable, so that fundamentally it seems reasonable that during the next few years there will be an increase in the weight of driver axles on the Mikado type of engine. Some railroads already are using about 64 000 lb. per driver.

To obtain tractive power greater than that afforded by the Mikado, it is necessary to use more driver axles. This leads immediately to the 5-axle or Santa Fé engine, or the Mallet engine with its 6, 7, 8, or even 10 axles.

The extended wheel-base used with Mallet engines greatly reduces the bridge loading when compared with the E-60 loading. For floor systems and short spans, there is no such reduction with the 5-driver axle, or Santa Fé type.

In studying this matter a few years ago, the writer compiled the diagrams, shown on Fig. 15, which compare moment, shear, and floor-beam reactions for the following locomotives:

1.—A U. S. Railroad Administration, heavy, Mallet engine of the 2-8-8-2 type, assumed as representing about the heaviest Mallet engine that would be used, except at special locations to meet peculiar operating requirements.
2.—A Denver and Rio Grande Santa Fé engine weighing 428 500 lb. This was assumed as typical of the heaviest Santa Fé engines built. It should be noted that the wheel-base is somewhat extended.
3.—A typical Santa Fé engine with condensed wheel-base and 65 000 lb. per driver axle.
4.—A typical Santa Fé engine with condensed wheel-base and 60 000 lb. per driver axle.
5.—An E-60 loading.
6.—A special engine of the Pennsylvania Railroad, Santa Fé type, weighing 442 840 lb.

The plotting of data for the last engine was of no practical value. It was interesting as showing the percentage by which it exceeds other loadings more generally in use. These diagrams (Fig. 15), support the statement that for spans in excess of about 100 ft., an E-60 loading is about heavy enough, as far as trusses are concerned, regardless of type of engine or weight of drivers. However, these diagrams also show that for a concentration of five axles on a 20-ft. wheel-base, with 65 000 lb. per axle, the loading demand for floor sys-

tems of all bridges and for many short spans is from 15 to 20% greater than that provided for by the E-60 design.

Five 65 000-lb. driver axle loads, spaced at 5 ft., with a condensed wheel-base for the entire locomotive and tender, will protect all the engines commonly used. Under certain types of locomotives, the loading will give extra strength in the floor system and hangers of truss bridges, and in short spans. This will give only needed protection to such metal against corrosion. Even if the life of a steel bridge is assumed to be only 30 years, the loss of strength of floor systems in that time is alarming. The menace of corrosion, resulting from brine drippings, and from a policy of paint maintenance controlled by the net income of a railroad, would justify the use of reduced unit stresses in the design of such parts. Certainly, it demands that floor systems be originally designed so that they will not be weak under engines which represent 15 to 25% of those purchased in the last four years.

Regardless of criticism of the heavy loading proposed by the author, it appears to be self-evident that the E-60 designs are outgrown as a protection to the types of engines in service. The Committee on Iron and Steel Structures of the American Railway Engineering Association has defended the retention of the Cooper system of loading, in spite of representations as to its inadequacy to protect the Santa Fé engines. Criticism has been answered by the statement that the loading of the Santa Fé engines will be protected by the use of the E-65 loading instead of the E-60. As the author has clearly pointed out, this results in a loading for long bridge spans, which is excessive, and an increase in uniform train load, which is not warranted.

A fundamental psychological factor is further involved which should not be ignored. For years, executive officers, and transportation officials generally, have associated the E-50 and E-60 loadings with corresponding axle loads of 50 000 and 60 000 lb. It is unreasonable to expect that such executive officers will understand and approve a loading called the E-65, which does not protect axle loads of 65 000 lb. Further, it is extremely difficult to obtain the approval of expenditures when the implied loading is decidedly greater than the axle loading of the engines in use, or those likely to be purchased.

Railroad officials generally are being educated to the fact that new bridges designed for ordinary unit stresses have a factor of safety sufficient to allow the operation of any type of engine or weight of driver axle. Such officials, naturally, cannot be expected to be particularly interested in consistency of design which will permit a proportional increase of axle load for all types of engines operated. It is the function of the Profession, and railroad bridge engineers in particular, to recommend such loading as will be consistent for all types of power which are likely to be operated and which, at the same time, will appeal to financial and executive officials as properly conservative and based on axle loads of modern heavy power.

It is to be hoped that, in the discussion of this paper, criticism of the extreme high loading which the author recommends shall not be allowed to cloud the essential facts which he has so ably presented, namely, the inadequacy of the Cooper system of loading at ordinary unit stresses of design properly

to care for the present engine loading and for such engine loading as may reasonably be expected in the next five or ten years.

J. A. L. WADDELL,* M. AM. SOC. C. E. (by letter).—During the last four decades, the evolution in America in bridge designing has been marked from time to time by certain epoch-making papers, usually presented to the Society and thoroughly discussed by its members. To these papers and their discussions is mainly due the development of bridgework from a crude art to an advanced science.

This paper is worthy of being included in the list of such epoch-making papers. The Society and the Profession are deeply indebted to the author for his praiseworthy altruism in undertaking such an important investigation. The writer, for the last forty years, has been making somewhat similar studies. As long ago as 1892, in a paper entitled, "Some Disputed Points in Railway Bridge Designing"†, he treated at considerable length the subjects of railway bridge loadings and equivalent uniform live loads. Following the publication of that paper, he extended his investigations, and, later, wrote a pamphlet entitled "The Compromise Standard System of Live Loads for Railway Bridges and the Equivalents for Same." This pamphlet evoked much discussion in the technical press, as some engineers were opposed to the use of equivalent loadings, deeming exactness of stresses to be a *sine qua non*, and seeming to forget that all assumed loadings are merely typical and that they will never be more than approximately realized.

The result of the original papers and the ensuing numerous (and often quite warm) discussions was eventually to bring into general use the simple and economic method of calculating live load stresses in bridges by the use of equivalent uniform loads. In those days, that method was much more accurate than it is at present, for three reasons:

First.—Both the maximum and the average span lengths were then much shorter than they are now.

Second.—The weight per linear foot of the locomotives with their tenders did not then greatly exceed the weight per linear foot of the loaded cars, whereas, to-day, the excess is 50% or more.

Third.—Modern locomotives are longer than those in use three decades ago.

It goes without saying that the greater the excess of locomotive weight, as compared with that of a corresponding length of loaded cars, the greater will be the variations of stresses computed by the two systems—wheel loadings and equivalent uniform loads.

Comparing Mr. Steinman's investigation with that of the writer previously mentioned, there is as great a variation between them, in respect both to importance and science of treatment, as there is in the weights of present-day locomotives and those of that time.

The author has shown that the "Cooper" loadings should be relegated to oblivion; and, in the writer's opinion, the proposed new system is as good as

* Cons. Engr., New York City.

† *Transactions*, Am. Soc. C. E., Vol. XXVI (1892), p. 77.

can be evolved for the purpose of bridge designing. The argument suggested as a reason for retaining the Cooper loading, namely, "that it affords a convenient standard for rating bridges", is unsound, because the author's M-60 loading, with its proportionate M-10 unit loading, provides just as convenient a rating standard.

The "rating standard" evolved by Charles F. Loweth, President, Am. Soc. C. E., deserves to be considered as one of the "epoch-making" investigations in the evolution of bridgework, notwithstanding the fact that it is disassociated from designing.

Concerning the author's three suggested loadings, the writer is opposed to Loading No. 2 as being unscientific and illogical. It has no *raison d'être*, for it is much more troublesome to use than the equivalent-uniform-load method, and is but little, if any, more accurate.

As for Loading No. 1, it is well to retain it and include it in the specifications as the typical wheel loading, but it should be clearly stated therein that it is not to be used in computing stresses.

Loading No. 3 is by far the best, and should be generally adopted. As stated by the author, it is "the most scientific in principle and most convenient in application." In the writer's opinion, this claim cannot be gainsaid.

The specifying of a live load shown by wheel diagram and using instead a loading indicated by a formula that agrees therewith only approximately, may be objectionable to some engineers; but what does it matter if there is an occasional difference of a few per cent. between the two methods when both methods are merely arbitrary assumptions? To overcome this objection and satisfy the quibblers, let the formula be called the true standard and the wheel diagram its approximate graphic representation.

The thoroughness of the author's investigation and the clearness of his presentation of findings mark this paper as one of the best ever submitted to the Society.

GUSTAV LINDENTHAL,* M. AM. SOC. C. E. (by letter).—The author's painstaking analysis of the different locomotive loadings in use for the design of American railroad bridges is a valuable contribution to a subject which has been discussed for a long time, but which is not as vexing as is usually assumed.

The Cooper standard has become conventional, because it is sufficiently inclusive of maximum effects from concentrated loadings of locomotives and the grouping of such loadings. When locomotives become heavier, it is convenient to assume heavier axle loads without disturbing the grouping. Some locomotive axle loads have already reached nearly 80 000 lb. and some groupings of wheel loads, 370 000 lb. in 22 ft. There may be further increases in loads and changes in wheel spacing that cannot be foreseen. At times, bridges have to carry whole trains of dead locomotives. Meticulous accuracy, therefore, is out of place.

The author's proposed first method, substituting a new and simpler wheel-load diagram for the Cooper diagram, seems preferable to his other two pro-

* Cons. Engr., New York City.

posed methods. It would represent the smallest departure from present methods and is sufficiently inclusive of the maximum effects of loads from any of the seven locomotive-wheel diagrams illustrated in his paper. The Cooper diagram should also be illustrated in this paper, so that bridge engineers of other countries may know without searching elsewhere what the Cooper E-60 loading represents. Trusses in longer spans are less affected by the heavier locomotives than those of shorter spans, as may also be seen from Figs. 6 and 9.

The floor construction is merely a succession of short spans, therefore, it suffers more than the trusses from an increase of locomotive weights. The larger allowance for impact in floor members covers, to a certain extent, unforeseen increases in wheel loads.

Fast trains which produce the largest impact stresses, usually have lighter locomotives. The heavy locomotives considered by the author are used only with freight trains, usually at only one-half the speed of passenger trains, therefore, smaller impact stresses are produced. It is probable that heavy axle loads plus impact produce smaller stresses than the lighter passenger locomotives plus impact, at 50 to 60 miles per hour.

R. A. Caughey,* M. Am. Soc. C. E. (by letter).—The writer believes that Mr. Steinman has made a wonderful contribution to the Profession in the preparation of his paper and has done a great deal toward making changes in loadings for railway bridges, which many engineers have recognized as necessary, but have been unable to suggest on account of the enormous amount of work involved. He has proved that the Cooper loading should be replaced by one more in accordance with the weights and axle arrangements of modern railway rolling stock. He has also developed an equivalent uniform load which is really "equivalent", as he has taken into account the position of the section at which shear or moment is desired. Perhaps, it would be more accurate to say that three systems of equivalent loading have been developed, giving design results far more satisfactory than those of the Cooper system.

As to which of these systems it would be best to adopt, the writer would favor the first, the M-engine diagram, and might be criticized for doing so, as it would seem that either of the last two loadings would be easier to apply. This would be true under ordinary circumstances, but with a chart available, such as is given by the author on Plate X, and a table of equivalent uniform loads, such as that given in Fig. 2, no one who dislikes the long computations involved in stresses due to wheel loads would be forced to make them.

In many cases, the position of the engine loading (even though hypothetical) on the structure is desired and of the three schemes suggested the first is the only one which would give this. One case in which such information would be desired would be that of a complicated structure having a broken influence line some segments of which would represent positive and others negative stress and in which the maximum stress would have to be determined by trial positions of the engine and train.

* Associate Prof., Structural Eng., Iowa State Coll., Ames, Iowa.

Another point in favor of the engine diagram, the writer believes, is that it keeps the computer more in touch with the principles involved in the computation of stresses due to moving loads; and it is his belief that the engineer who computes stresses without an understanding of the underlying principles is of little use to his employer. If the first method was in vogue, any computer would have the equivalent load as a time-saver and still not lose sight of the loading producing it.

The officials of some roads prefer to use their own engine diagrams in the design of bridges, and no doubt they would find the engine diagram closer to the conditions with which they deal and could use it best as a basis of comparison with their loadings. In such cases, the engine diagram would be the basis for "short cuts" such as equivalent uniform load charts and tables, and it would seem that it should be and could be so in the case of the M-loadings.

To sum up, it is the writer's belief that a change in bridge loadings should be made and that a simple, tangible system should be adopted. Much could be said for the simplicity of the third method, but it is a question as to whether railway bridge designers would care to think of a bridge loading as a thing so intangible as to be represented by an equation, and it may also be noticed on investigation that, for certain conditions, there is considerable variation from the "composite" loading when the equation is used. It seems that by the use of the author's charts, tables, etc., the first method will satisfy all requirements of simplicity and tangibility, will give a loading approximating most closely the "composite" loading, and, in addition, will be easy to use in bridge specifications.

While on the subject of railway bridge loadings, the writer wishes to state that, on branch roads, the controlling load in the design of bridges, especially short-span bridges, is the train load instead of the engine. To illustrate this, compute the maximum live load bending moment at the center of a 40-ft. plate-girder span, the traffic on which consists of an engine load followed by Pennsylvania railroad gondola cars of 220 000 lb. capacity, with an allowance of 10% for overload. The weight of these cars is 74 600 lb. It will be assumed that the engine is equivalent to Cooper's E-50. According to Table 3, a Cooper E-64 engine is equivalent to an M-50 loading when the center moment on a 40-ft. beam is considered. An E-50 engine, therefore, would be equivalent to $\frac{50}{64} \times 50 = 39$, say, M-40. The center moment due to a train of the coal cars mentioned will exceed nearly 15% that of the M-40 engine loading. From this, it would seem that attention should be given to this type of loading as well as to locomotive loading, especially when light locomotives are used.

J. C. Ralston,* M. Am. Soc. C. E. (by letter).—This paper embodies a comprehensive if not a conclusive re-cast of a question which heretofore has been in a state of general flux. As a comparative study, with a re-valuation of the essential factors, lighted by the last word of the mechanical or motive power engineer, and evaluated by the theory of probabilities in future loco-

* Const. Engr., Spokane, Wash.

motive development, it is likely to clarify and standardize future specifications on loadings for many years.

Viewing the paper from the human standpoint of ethical ambition on the part of the author, it is expressive of the best devotional spirit of the Profession. Too often this spirit of contribution is lost sight of by the reviewer who would apply his own yard-stick in measuring engineering worth. Happily, this paper is timely, because it is serviceable in a practical way.

The redemption and the inspiration of the Profession lie in the contribution of a definite, usable, and needed technical asset. When such contributions are inspired by altruistic vision rather than profit, the genius of a great profession is finding its most lofty expression.

It is in this larger sense that the writer would commend the author. He has shown the erratics of the Cooper applications, or, as he states, "smoothed out the depressions," and given the bridge designer a more consistent and logical procedure for the determination of his controlling stresses.

It is safe to assume that the equivalent uniform loadings, applied either directly or through the author's so-called Composite, will stand for a long time.

The engineering offices of the motive power departments generally are turning their attention to the details of boiler and cylinder performances, to the metallurgy and the re-design of revolving and reciprocating parts, and to special devices, rather than to any further increase in or multiplication of axle concentrations. Road structures and clearances are putting a peremptory estoppel on further swelling the bulk dimensions of locomotives. Mechanical and energic improvements of locomotives have been delayed too long, but the obsession is now and will be toward carrying them to maximum finality.

The ratios between heating surfaces, grate areas, and cylinder volumes have been digested and re-digested carefully. At present, and hereafter, the mandatory is on that of providing a gas to produce the greatest cylinder horsepower and of obtaining greater calorific results per cubic foot of firebox volume. Pyramiding further axle concentrations on top of obsolete steaming practice is in limbo. These considerations being true, the railway bridge designer may look forward with confidence to an extended period for the application of the author's thesis.

Railway engineering has not been confined to the bold projects of territorial penetration, nor to the conquest of rugged and intransitable gorges, but covers also those masterful exploits which the patience, ingenuity, and genius of the mechanical engineer and the bridge engineer have accomplished. It has been an Augustan Age from the days of "Puffing Billy", the grass-hopper locomotive, to this hour of the super-Mallet and its concomitants, the colossal cantilever or the awe-inspiring arch. The "Rocket" locomotive of 1830, weighing 4½ tons, and the "Old Ironsides" of 1832, weighing 5½ tons, were feeble but epochal beginnings. Ten years later, the pace had been trebled. In 1842, Matthias Baldwin built for the Georgia Railroad, on order from J. Edgar Thomson, its Chief Engineer, fourteen of those famous "6-wheels-connected" locomotives. They weighed 12 tons each, or 4 tons per axle. Messrs. Thomson, Latrobe, and others of those days, and, later, Meigs, Fink, Bollman, Howe,

and their contemporaries were making great strides in bridge design. Yet, the work of each has become obsolete and inadequate practice. Newer and better engines and stronger and bigger bridges were demanded. Within the last decade, the bridge designer must draw his specifications for the requirements of locomotives with two and even three groups of drivers, each engaging four or five axles under concentrations of 60, 70, or 80 tons, and some ponderous machines weighed as much as 449 tons—one hundred times more than the original locomotive.

J. C. BLAND,* M. AM. SOC. C. E. (by letter).—In the Cooper specifications of 1890, the two heaviest loadings used were the "Lehigh Heavy Grade Engine Class" and "Class Extra Heavy A". Each loading consisted of two coupled Consolidation engines followed by a train designated as so many pounds per linear foot of track. Each engine was 32 ft. 7 in. long, with a tender 20 ft. 10 in. long.

The "Lehigh Heavy Grade" engine weighed as follows:

Pony truck	16 000 lb.
4 driver axles, at 40 000 lb.	160 000 "
2 tender axles, at 18 000 lb.	36 000 "
2 " " , at 20 000 lb.	40 000 "
Total	252 000 lb.

The train load was 4 000 lb. per lin. ft.

The "Class Extra Heavy A" weighed as follows:

Pony truck	16 000 lb.
4 driver axles, at 30 000 lb.	120 000 "
4 tender axles, at 18 000 lb.	72 000 "
Total	208 000 lb.

The train load was 3 000 lb. per lin. ft.

In 1894, in his paper entitled, "Train Loadings for Railway Bridges",† Cooper proposed the loading which since has been so generally used. This loading consisted of two coupled Consolidation engines, the length of the engine being 34 ft. and that of the tender, 22 ft. The train load was given as so many pounds per linear foot of track.

In this loading, the various axle loads were expressed in terms of the driver axle load considered as unity, that is, the pony truck axle load was 0.5; each of the four driver axles was 1.0; and each of the four tender axle loads was 0.65. Thus, the weight of the engine was 4.50 units; that of the tender 2.60 units, and the train weight per linear foot was 0.10 units. Cooper gave as a minimum the E-25, and as a maximum the E-40, loading. He seemed to have considered the latter the heaviest loading possible, and expressly said so regarding the train load of 4 000 lb. per lin. ft.

When the axle loads increased between the limits named, there was no change in the axle spacing, therefore, in computing moments, shear, etc., for

* Engr. of Bridges and Bldgs., Pennsylvania System, Pittsburgh, Pa.

† *Transactions*, Am. Soc. C. E., Vol. XXXI (1894), p. 174.

unit loads for this axle spacing, the finding of these functions for any E-loading was merely a matter of multiplication.

The advantages of this loading are many, but the disadvantages are:

(1).—That even in 1894, the ratio of tender axle load to driver axle load of 0.65 was smaller than that in actual engines; and the distance between the rear driver axle and front tender axle of 9 ft. was 30% less than in actual engines of the Consolidation type.

(2).—The weight of the train per linear foot was given as one-tenth the driver axle load, that is, the train load is a fixed proportion of the driver axle load.

(3).—The method was clearly inapplicable to engines of a type different from that assumed, namely, the Consolidation type.

As the weight of engines of the same type increases, the wheel-base and length increase, and although this is of not much account between the limits given by Cooper in 1894 for his proposed loading (namely, from E-25 to E-40), it becomes of consequence beyond E-40. In short, the E-loading is not applicable beyond Cooper's upper limit.

As to the train, there is no necessary relation between the weight of train per linear foot and the driver axle load, or, more generally, the weight on the driver axles. The gross weight of the train as a whole depends on the tractive power, and that again depends on the load on the drivers. Within the limits of the Cooper proposed loading of 1894 (E-25 to E-40), this did not make much difference, as E-40 engines were generally hauling 4 000-lb. trains, but the principle cannot be extended to E-60 engines, or greater.

In his paper, previously mentioned, Cooper wisely remarks that "the tendency to seek for a 'final standard' in any engineering construction, regardless of changing conditions, is a harmful one," and, by the same token, the writer considers that for many years the "Cooper loading" has ceased to be a standard. He concurs with the author when he states that "the time has come to make a fresh start, with a system based on the existing locomotive and train loads", and the writer feels confident, that if Mr. Cooper was still alive, he would share this view and be among the first to devise a new method and one which not only conformed to existing engines and train loads, but looked forward and beyond. The author's paper is so complete as to leave little room for discussion.

The writer studied the effects of some of the heaviest engines and train loads of the Pennsylvania System, and prepared a diagram which showed the "Cooper index" or "equivalent" for each foot of span up to 300 ft., for bending moments, shears, and cross-girder re-actions. The great variation of the "Index" for the same engine fully exhibits the inadequacy of the "Cooper loading" to represent the stress effects of modern heavy engines and trains. Table 9 gives the principal data for the heavy engines of the Pennsylvania System, as compared with the Cooper E-60.

Apparently, Cooper did not look forward to the use of engines other than those of the Consolidation (2-8-0) type, and the data given for the heaviest engine of that type used on the Pennsylvania System (the H-10-s), show the

great difference in many of the ratios, which, on the supposition of extending the Cooper system of loading beyond the E-40 given in his paper previously mentioned, should be the same.

The H-10-s engine has a Cooper equivalent or index of E-55 to E-50, and being of the Consolidation type, naturally shows less variation in the index than the engines of different types. Nevertheless, there are wide divergences in the ratios. The Cooper engine weighs 7.10 times the driver axle load, whereas, the H-10-s weighs 7.61 times the mean axle load. The Cooper tender weighs 2.60 times the driver axle load, whereas, the tender of the H-10-s weighs 3.18 times the mean driver axle load, or, expressed differently, the Cooper tender axle load is 65% of the driver axle load, whereas, the H-10-s tender axle load is 79.6% of the mean driver axle load.

It would be hardly fair to dwell on the divergences of the ratios of engines of other types from the Cooper ratios. One could scarcely expect to find a Consolidation engine of the Cooper type, which would produce the same stress effects as those caused by such an engine as the N-1-s; therefore, it is here that the author's suggested loading seems to fulfill the requirements. He makes a "composite" of all the heavy engines, and finds a loading which will come measurably close to the moments, shears, etc., caused by this "composite"; thus, all the irregularities of the actual engines are eliminated. Of the three forms of loading presented by Mr. Steinman for replacing the Cooper E-loading, the writer much prefers the third.

The Cooper loading has been of incalculable service, not indeed for the design of bridges, but for expressing the capacity of existing bridges. It has furnished a base, now fully understood by railroad men, whereby structures may be classified and compared. By taking an actual engine and determining the stresses in each member of an existing structure, and then by dividing each stress, moment, or shear, etc., by those due to the Cooper E-1, the Cooper index for each member is obtained, the lowest of which gives the capacity of the bridge. Any other typical engine would do as a base, but the Cooper engine serves the purpose far better, principally because of its general acceptance.

With the introduction, some years later, of engines with trailers, and also of engines of the Mallet type, the use of Consolidation engines for the design of bridges could hardly be maintained as good practice, and such railroads as had adopted the Cooper loadings as their standard were soon compelled to use different Cooper loadings for the different parts of the same bridge, as is pointed out by the author. Such a practice is not desirable.

The defects of the Cooper loading for the design of bridges having been so clearly shown by Mr. Steinman, the writer hopes that one of the three methods presented will soon be adopted by the Profession. The writer earnestly desires the abandonment of the Cooper loading for the design of new bridges of a capacity greater than E-40, but he has no such wish with reference to its use in stating the maximum capacity of existing structures; in short, the Cooper loading should still be maintained for use as the base of reference.

NOTE.—Tractive power for mean effective pressure = 85% of the boiler pressure, except in cases of the I-1-s and the H-C-1-s. For the I-1-s, the tractive power = 75% of the boiler pressure, and for the H-C-1-s, it is based on weight on drivers.

With reference to the design of structures, the writer wishes that each railroad would consider the group of its engines for which it desires to provide, form a "composite" of such engines, and then choose the M-loading (taking into account future development) that best fits its case, and use such loading in its specifications.

"Taking into account future development," stated previously, presents a problem. Shall a given percentage be added to each of the engines forming the "composite"? Or, shall only those of the group which one thinks will in time be increased be considered? The easy way would be to increase each one of the group by a given percentage—the better way is to consider the question further. The Mikado engine is a Consolidation engine with an added axle—the trailer—which in a sense may be called non-productive weight, as it does not increase the adhesion of the drivers. In the I-1-s engine, however, the added axle is a driver, and, therefore, the adhesion is increased.

Comparing the L-1-s engine with its predecessor the H-10-s, the weight on the drivers was increased only 9½%, while the weight of the engine increased 32%, and the tractive power increased only 16 per cent. Comparing the I-1-s engine with the H-10-s, the weight on the drivers increased 41%, and the weight of the engine increased 45%, whereas, the tractive power increased 69 per cent. The I-1-s would seem a better and more economical development than the L-1-s.

Again, compare the N-1-s with the H-10-s. The weight on the drivers increased 47%; the weight of the engine increased 70%; and the tractive power increased 60 per cent. This does not seem as economical a development as the I-1-s, and although the I-1-s weighs 96% of the N-1-s, its tractive power is 6% greater, and the weight of engine per pound of tractive power is 4.12 as against 5.12 for the N-1-s; that is, a pound weight of the I-1-s is more productive than a pound weight of the N-1-s.

Thus, it would seem that the I-1-s type of engine is more likely to be increased in the future than the L-1-s or N-1-s types.

The stress effects of the I-1-s type do not differ much from those of the N-1-s; therefore, it is immaterial if both were increased in the same proportion. Prognosis as to engine development, however, is extremely hazardous, the writer merely presents the facts as they stand to-day and ventures a few comments.

J. M. Johnson,* M. Am. Soc. C. E. (by letter).—The author presents, in a convincing manner, the defects of the Cooper system of rating as applied to many of the present-day locomotives. The writer agrees with this indictment, if it is confined to those roads having a heavy and steady tonnage, consisting principally of coal, ore, and furnace products, requiring for its economical movement, under diverse conditions, the various locomotives (seven in number) tabulated by the author. For such roads, the Cooper rating fails, or is unsatisfactory, and could be replaced with advantage by the author's system, based on any one of the three proposed loadings.

* Marion, S. C.

There is, however, a large mileage in the South, Southwest, and parts of the West, constructed, of necessity, originally with a large curvature and with comparatively light rails. Also, from necessity, this condition is likely to remain practically unchanged for some time. On many of the roads in this territory, the heaviest power is of the Mikado and Mountain types of locomotives, the curves (shear and moment) of which agree quite closely with the Consolidation type of equal axle loads, and, in consequence, the Cooper loading gives satisfactory working results. On other roads of the same region, in addition to the Mikado and Mountain types, 2-10-2 locomotives with maximum axle loads of about 60 000 lb. are in use on divisions where the curves are not too sharp. The shear and moment curves of this engine, for equal axle loads, are somewhat above the Cooper curves, but the difference between the curves when only one 2-10-2 locomotive is used, is not marked, except for short spans. Engines heavier than the three types mentioned would have no place on these roads, except that occasionally a locomotive of the Mallet type is used as a pusher on a mountain grade.

C. D. Purdon, M. Am. Soc. C. E., investigated the relation between the Cooper loading, and various heavy locomotives, with axle loads averaging 55 000 lb. The result of this investigation is shown by curves, originally published in *Engineering News* of October 23, 1913, from which it is interesting to note the practical agreement of the Consolidation and Mikado curves, and the decided departure of the E-55 curve, from that of the Consolidation engine as usually built. The curve of the Decapod—the nearest to the general 2-10-2 engine—is above the Cooper diagram for girder spans, but below it for truss spans. A study of these curves leads to the conclusion that, for the Mikado and 2-10-2 engines, with axle loads of about 60 000 lb., the Cooper loading gives satisfactory results.

The writer believes that the loading suggested by the author is in the right direction, but thinks its application now to the entire country is too radical, inasmuch as there is a large mileage for which the Cooper loadings will be satisfactory for a long time.

C. S. G. Rogers,* Esq. (by letter).—The author of this interesting paper presents the inconsistencies of stress resulting from applying a conventional engine loading and wheel-base such as that of Cooper, to the design of bridges which are to carry engines of axle loadings and wheel spacings relatively so different from the conventional loading.

The new loading, M-60, appears amply to cover all stresses in all lengths of spans that may result from the use of five of the heaviest, present-day types of engines. If all these five types of locomotives were in use on any one railroad, the proposed conventional loading would admirably conform to the requirements. Is this the case, however? Is it not rather that each railroad appears to be developing its engines along lines peculiar to itself?

The force of the author's arguments, therefore, seems to point, not to a conventional engine loading that will prove satisfactory, no matter what type of locomotive is used, but rather to loadings that will specifically meet the

* Bridge Engr., Canadian National Rys., Eastern Lines, Moncton, N. B., Canada.

type of locomotive peculiar to the railway under consideration. Unless this is done, the extra material put into the bridge structure to suit the requirements of engine loadings of foreign roads is a direct and needless waste and will never be called on to function.

It is noted, too, that although the main argument centers about the new conventional loading, M-60, other loadings proportional to the front group of drivers and to the uniform train load are recommended for those railways the locomotives of which are not of the size of the five heaviest under consideration.

The fact is, however, that where the engines used are of a less powerful type, they are not merely reduced models of these heavier types (2-8-8-8-2, 2-10-10-2, 2-10-2, etc.), but usually have different groupings of drivers. The problem, therefore, does not appear to be solved by adopting a loading lighter and regularly proportional to M-60, but rather in discovering a loading which will conform to the various locomotives in use or likely to be used on the special railway under consideration. No one of the five railways, the heavy locomotives of which have been considered in developing the M-60 loading, is concerned in making its bridges strong enough to carry the heavy locomotives of the other four railways.

Looking at the matter from another angle, it is shown that the Cooper E-60 loading nearly satisfies the stress requirements for these five heavy engines for the longer spans, yet would leave an over-stress of approximately 25% in some of the shorter spans. Conversely, should the engines in use on any railroad reasonably conform to any of the Cooper loadings (a not unreasonable supposition), the use of the M-60 loading (or one of a proportionate series) would result, in the shorter spans, in a waste of the 25% excess material that the M-60 loading would provide. Therefore, from this point of view, too, the adoption of the M-60 loading is not the real cure for the evils resulting from a loading that does not conform to the actual loading, and the problem still appears to be the discovery, on the part of each railroad, of a conventional loading to satisfy its special needs.

The author, however, has made a valuable contribution to the problem of bridge design in so forcibly calling to the attention of the bridge engineer the inconsistencies resulting from adopting an arbitrary engine-loading diagram without carefully analyzing, on a percentage basis, the relation between the stresses produced by the heavier or critical engines in actual use on the lines under his jurisdiction and those produced by the conventional engine, and correcting the latter before adoption.

E. A. Stone,* Esq. (by letter).—The author's reasons for classifying the Cooper system of loading among the relics of the past seem to be beyond dispute, and, therefore, his proposed new loading system is a long step in the direction of filling a recognized need.

The three solutions of this problem indicated in the paper probably cover, in general, all methods that might be brought forward. The first method, a wheel-load diagram, would be a continuation of present practice and, after having made up a table such as that shown in Fig. 2, it would be as simple to apply as any other method.

* Montreal, Que., Canada.

The author is entitled to the sincere thanks of all bridge engineers for the exhaustive manner in which he has presented this subject, particularly in the tables and diagrams.

Would it not be desirable and opportune, in view of the present state of bridge specification loadings, to appoint a committee to consider this matter fully and endorse the author's proposed M-60 loading, or bring forward some other loading which might be deemed preferable?

HAROLD C. BIRD,* ASSOC. M. AM. SOC. C. E. (by letter).—For more than thirty years the subject of concentrated wheel loads has been discussed. This paper, fortunately, comes at a time when members of the Society are interested in the adoption of a new specification for bridge design and construction.

When the late Theodore Cooper, M. Am. Soc. C. E., first specified his Class A and B as Consolidation locomotives, he probably did not anticipate that the Consolidation type of locomotive would be the type governing bridge design for so many years. Familiarity with the Cooper series should not prevent the adoption of another live load specification if the latter more nearly fits the needs. The idea of any load system specified is not to represent an actual engine or train, but to be an imaginary group of wheels (or its equivalent) which should give as great, if not greater, stresses than any which are likely to occur at present or in the immediate future. If the Cooper loading does this, and does it economically, there is no reason to make change.

The author has treated the subject in a thorough and enlightening manner which should convince those who will permit themselves to be convinced, that the Cooper loading does not carry out the idea expressed previously, nor does it fit the needs for rating bridges. The fact that there was difficulty in the shipping of some of the new locomotives is another indication that bridges are not prepared to carry the loads of the present time.

Although the writer has used Mr. Steinman's charts (similar to Plate IV) in the classroom for several years and has felt that they are satisfactory, he imagines that many engineers have never used them, and thinks it would be well if the author would illustrate the use of the charts with typical problems and show how they are plotted. The writer notices that the tables are not labeled with longer and shorter segments, which is an oversight.

The discussion† by F. E. Turneaure, M. Am. Soc. C. E., on the Specifications for Steel Railway Bridges submitted by the Special Committee on Specifications for Bridge Design and Construction, or the original,‡ should be referred to by all those studying this paper. The writer has calculated a number of cases using Mr. Steinman's proposed series and has been pleased to note how well the values fit the maximums of the moment and shear diagrams of the American Railway Engineering Association. The making of such diagrams and especially the calculation of shear and moment tables similar to those in Ketchum's "Structural Engineers' Handbook," would be a helpful addition to the paper.

---

* Prof. of Civ. Eng., Pennsylvania Military Coll., Chester, Pa.

† See p. 532.

‡ *Proceedings*, Am. Ry. Eng. Assoc., Vol. XXI.

The paper will also serve somewhat as a stop to the arguments as to whether concentrated wheel loads, equivalent uniform, or a uniform load with excess or excesses should be used, for, here, engineers can have their choice, with results practically identical. This will give those who so desire, an opportunity to visualize and, in addition, will offer those who desire excess loading, an opportunity to have their way. The formula submitted should also merit a great deal of attention.

The idea suggested by Henry B. Seaman, M. Am. Soc. C. E., that live loads shall consist of either the Cooper or the Steinman series, as may be specified by the engineer, is a good one.

If nothing else is accomplished by this paper, engineers have been given an easy way to compare the stresses produced by the Cooper series with those produced by the heavy engines of to-day.

ALMON H. FULLER,* M. AM. SOC. C. E. (by letter).—It is difficult to foresee the far-reaching effect of this paper. The Cooper loading no longer represents even to an approximate degree the modern locomotives and trains; it is still used, first, because it has been used; second, because tables and diagrams are available for ready computations; and, third, because nothing better has been offered.

It now seems apparent that the third reason has been removed by the presentation of this paper. The second reason is also partly met by the tables and diagrams which have been presented by the author. Other tables, such as moments and shears for various panel lengths and numbers of panels for truss work and for moments, shears, and floor-beam reactions for girder spans, may be constructed, the work on which would be insignificant in comparison with its importance. The first reason has very little validity beyond that of natural inertia, and to persist in the use of this obsolete standard would be not only unscientific, but would result in uneconomical designs.

Of the three suggestions which Mr. Steinman has offered, one may likely have difficulty in making a choice. The writer would eliminate the second suggestion; although it has the merits claimed by the author, it lacks the definite picture presented with the first and the scientific background of the third suggestion. The writer has tried to get the viewpoint which evidently leads Mr. Steinman to prefer the third, but has yet been unable to do so to the extent of giving up the concrete picture presented by the first suggestion.

It is true that the formula would prove to be a "time saver" (for certain classes of work), that its scientific foundation yields curves of greater regularity and smoothness, and that it is independent of reference books to a certain extent. In these days, little designing or stress computation is done, or need be done, without access to an office library. When the tables and diagrams of the paper have been supplemented by the tables† for moments and shears adaptable to structures with panels presented to the Society by O. E. Selby, Jun. Am. Soc. C. E., and by girder tables for shears, moments, and floor-beam reactions, such as are now so generally available for the Cooper

* Prof. of Civ. Eng., Iowa State Coll., Ames, Iowa.

† *Transactions*, Am. Soc. C. E., Vol. XLII (1899), p. 223.

loading, the work of computation will be as simple for the engine diagram as for the formula. The diagram will be much more expressive than a formula on a drawing or in a specification. The fact that the formula gives a different uniform load for various parts of the same span, makes it necessary to refer to tables or diagrams for rapid work, and the use of the table or diagram will require as much time from one as from the other. Even though general use shall be based on the engine diagram, the formula, either in memory or in notebook, will be a convenient device for computations which must sometimes be made quickly and without office facilities. The author apparently had this in mind in referring to it as a "time saver." The writer wishes in no way to depreciate the ingenuity of Mr. Steinman in establishing this formula. He recognizes it as an asset in putting a finish on the entire discussion and in having a legitimate practical application as previously noted. He believes, however, that the greatest contribution from a practical standpoint lies in the first suggestion for a definite engine diagram.

After another half century or so, this diagram may represent existing loads no better than that of Cooper does at present. If that should be the case, the Profession, perhaps, will find it worth while to make another re-adjustment, and in doing so, this paper should prove to be of great assistance. If the author can show that the formula may be readily extended to rapidly changing situations, it would not only be an added reason for adopting the third suggestion, but, perhaps, the controlling one as well.

CARLTON T. BISHOP,* M. AM. SOC. C. E. (by letter).—The author has shown that the Cooper loading has outgrown its usefulness. It has served its purpose well, but the modern loadings have not increased proportionately, and some change should be made. A much simpler form of loading could be devised to give results as satisfactory as those which the Cooper loading now gives, but this would not be sufficient. Any new loading should give approximately the same results as the actual loads which are likely to be used in the near or distant future.

The author has made an exhaustive study of existing loads and of the trend toward the future. He has devised a composite loading which appears to be satisfactory, but, best of all, he has developed a formula for equivalent loads, which has great possibilities. This formula, or its corresponding tables or diagrams, can be used more advantageously than the concentrated loads and gives consistently good, if not better, results. No one system of concentrated loads can give precise stresses for different actual loads, and the simpler equivalent uniform load seems much superior. Mr. Steinman has blazed the way by proposing a formula for uniform loads in terms of segments of the span, thus overcoming the principal objections to the use of such loads, that have heretofore been advanced. The stresses obtained from these new equivalent loads provide for any of the critical engines of to-day, and, probably, by proportion, for those of years to come.

The writer hopes that future specifications will give the live load in terms of such a formula as that suggested by the author. Before such adoption,

* Asst. Prof. Dept. of Civ. Eng., Sheffield Scientific School, Yale Univ., New Haven, Conn.

however, a committee should study the question and agree that the proposed formula is the best obtainable.

CLYDE W. MACCORNACK,* M. AM. SOC. C. E. (by letter).—The writer is much interested in this excellent paper which is one of the most valuable contributions to bridge engineering literature in the past twenty years. It has been generally recognized for some time that the Cooper loadings do not properly represent modern locomotive loadings. Pressure of daily work has no doubt prevented many engineers from making as careful an examination of this subject as they have wished, and they will welcome the data contained in the paper, which give facilities for making the necessary comparisons. It is to be hoped that, as a result of this paper, a more modern system of locomotive loading will be generally adopted.

A standard type of loading should represent within close limits the actual loads in use. The proposed wheel-load diagram appears to satisfy this condition. Methods of computing stresses by means of the engine diagram have been so fully developed that the labor involved is not an important consideration. The engine diagram, representing actual loads in service, should always be used in examining existing structures. It does not follow, however, that the engine diagram should necessarily be adopted for designing new bridges. Any system of loading which will give resulting stresses equivalent to those of locomotives in use, would appear to the writer fully to satisfy the requirements. If economical designs can be produced by a simpler loading, it should be substituted for the engine diagram.

It is of advantage to adopt a loading which would have the general characteristics of the actual loads on the structure. Bridge floors and short-span bridges without floors are subjected to direct loads from the locomotive drivers. In the writer's opinion, such parts and structures should be designed for the heaviest actual loads in service. The stresses in trusses and girder parts where the loads are applied through a floor system, reach the trusses and girders in the form of panel concentrations. This form of loading is as well represented by a uniform load as by a system of wheel loads. The writer believes that a system of wheel concentrations representing the heaviest loads in use should be adopted for bridge floors and for short spans without floors and that a uniform load should be used in designing all other bridge members. The computation of stresses for such a system of loading would be reduced to the simplest operations, and, at the same time, the visualization of the loadings would be retained in the designer's mind. A load formula such as that offered in the paper or, if preferred, modified to coincide more nearly with the composite loading, should give as satisfactory results as an engine diagram.

It is to be hoped that this paper will result in the adoption of a new standard system of loading representing modern locomotive loads. The important consideration is not the type of loading, whether it be an engine diagram or an equivalent uniform load formula, or any modification of these,

* Chf. Engr., Phœnix Bridge Co., Phœnixville, Pa.

but that the new loading be such that it will represent correctly conditions created by modern locomotives in all parts of the bridge structure.

C. P. DISNEY,* ESQ. (by letter).—Mr. Steinman is to be congratulated on having made such an exhaustive study of this subject. His proposals are practical and may be considered as a solution of the need for a system of calculating stresses in bridges, which is abreast of the present progressive development of locomotives and trains in the United States.

All three of the alternative proposals presented have distinctive advantages over present methods. The third proposal, however, seems to be ideal, as it is a formula which can be memorized and used, without tables or charts, to find the moments and shears at any point of a span by a simple slide-rule operation.

As regards the application of this proposed system of loading to Canadian railways, it would appear that, although Mr. Steinman's system could be modified to conform to locomotives and trains operated in Canada, the Santa Fé type is, the writer believes, about the limit, considering the capacity of road-beds and bridges, and this locomotive, with a train of 100-ton capacity cars, can still be taken care of by using the Cooper loading.

In a 200-ft., through truss span, the maximum difference between the stresses produced by the Cooper E-55 loading and the corresponding stresses produced by a double Santa Fé, with a 5 500-lb. following load, including the floor system, is only 5 per cent. The 5 500-lb. load can be considered as a train of 100-ton-capacity cars, which is the most severe probable condition of loading likely to occur on Canadian lines.

In conclusion, the writer would state that he considers Mr. Steinman's proposals to be in line with the advanced type of trains operated in the United States to-day, whereas the Cooper system conforms to the type of trains operated in Canada, which type seems likely to continue for many years.

O. H. AMMANN,† M. AM. SOC. C. E.—The loadings proposed by Mr. Steinman unquestionably have the advantage of greater simplicity over the Cooper loading. This advantage, however, would not be sufficient to justify the abandonment of a loading which has been widely adopted as a standard. Tables and diagrams for the Cooper loading, including those of the author for equivalent uniform loads, greatly simplify the calculation of stresses for that loading.

Examination of the elaborate data contained in the paper has not convinced the speaker that the Cooper engine loading is less representative of actual engines than that proposed by the author. On the contrary, he is more convinced than ever that it is futile to attempt to introduce a loading which embodies any marked improvement over that of Cooper.

Consider, first, the engines alone as affecting spans up to about 120 ft. The author's engine bears no greater similarity than does that of Cooper to any of the seven heaviest existing engines, not to mention the many other heavy engines, steam and electric, still in use, and those likely to be evolved in the future.

* Acting Bridge Engr., Canadian National Rys., Eastern Lines, Toronto, Ont., Canada.
† Cons. Engr., New York City.

The apparent improvement of the author's loading over the Cooper system is due to inconsistent presentation of the facts. The author condemns the Cooper loading on account of its discrepancies with existing individual heaviest engines, and emphasizes the close agreement between his M-60 loading and the composite of heaviest existing locomotives. He does not disclose the equally large discrepancies between the M-60 loading and individual heaviest existing engines, nor the equally close agreement between the Cooper loading and the composite of heaviest existing engines. All these facts are clearly shown on the two diagrams (Fig. 16), which are self-explanatory. These diagrams also show the small differences (only up to 6% for shears and 7% for moments) between the M-60 loading and its average equivalent, the Cooper E-72 loading.

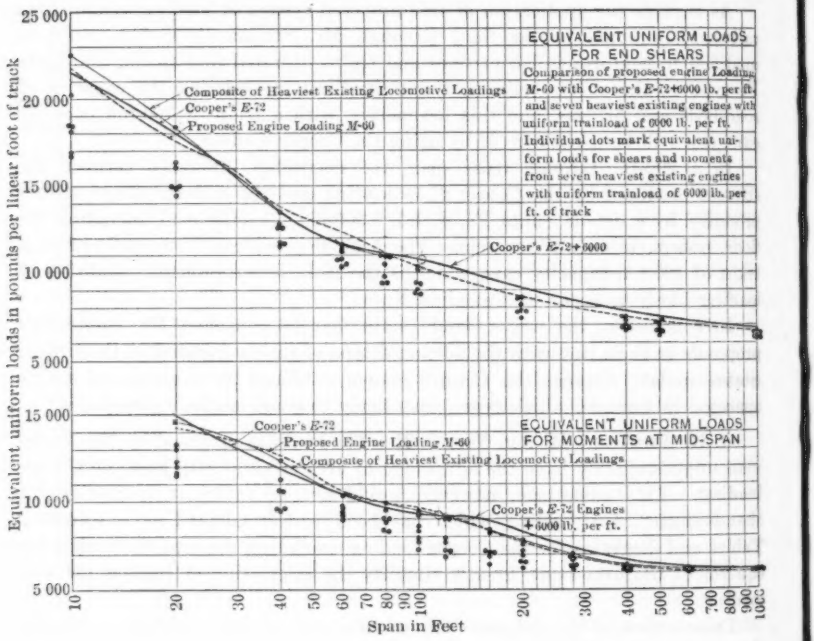

FIG. 16.

Considering the fact that differences between individual existing engines are several times larger, and also the many other uncertain factors, such as impact, wind, secondary stresses, quality of materials, etc., which factors, as variously specified, give, for the same live load, sections differing by as much as 40%, do these small differences between M-60 and E-72, even if they were improvements, justify the abandonment of an established loading?

Consider the combined engine and uniform train load: The apparent discrepancy between the Cooper loading and actual engines in short and long spans is not due to the Cooper engines, but to an inconsistent combination of

the engines and the uniform train load behind them. To represent the heaviest modern engines with a train load of 6 000 lb. per ft., as assumed by the author, and to compare equitably with the M-60 loading, the Cooper E-72 engines should be combined with the uniform train load of 6 000 lb. If that is done the apparent discrepancies of the Cooper loading and the existing heaviest loadings, for short and long spans disappear, as may be noted in Fig. 16. The Cooper curve is as smooth and follows as consistently the curve of composite heaviest existing loadings as the curve of the M-60 loading. Is there any guaranty that the weights of locomotives and cars will not continue to increase at different rates? If that should be the case, the author's loading would become as inconsistent as that of Cooper, unless its axle concentrations were also changed in a ratio different from that of its uniform train load. It is impossible to have an ideal loading for all conditions and all times. Loadings must be changed from time to time, but such changes should be made with the least possible disturbance of the generally adopted standard, unless commensurate advantages can be gained otherwise.

The speaker would recommend the retention of the Cooper loading, but would leave the variation of the engine concentrations and the uniform train load by suitable, not necessarily the same, ratios to the discretion of the engineer. Such a specification would be sufficiently elastic to cover practically any present or future loadings. This suggestion is not new, a different ratio for engine concentrations and uniform train load has already been used, notably in the design of the Metropolis Bridge.

The speaker would favor a formula for uniform load, except for the fact that such a formula does not convey to the mind a conception of the loading which it represents, and which is desirable for general comparison with actual engines. The author deserves much credit for his elaborate investigation without which proper judgment of this question would hardly be feasible.

HENRY B. SEAMAN,* M. AM. SOC. C. E.—The speaker wishes to express his appreciation of this paper. To have the subject presented in such detail is a great satisfaction.

The next question is its practical application and introduction. Bridges generally, throughout the United States, are rated on the Cooper E-system; all the records are on that basis, and to make such a radical change would hardly seem justifiable. Therefore, a double specification, providing for a multiple of either the E-10 or the M-10 loading, whichever may be preferred by the designing engineer, has been proposed by the speaker.

It is believed that future heavy bridges will be designed for the M-loading. It will not be difficult to alter the classified records of the railroads if the engineer so desires, as tables are furnished for that purpose. Mr. Steinman is to be congratulated on the results of his studies.

CHARLES A. MEAD,† M. AM. SOC. C. E.—The necessity for revision of the live loading for railroad bridges is becoming more and more apparent. Every

* Cons. Engr., New York City.

† Chf. Engr., Div. of Bridges and Grade Crossings, Board of Public Utility Commrs., Newark, N. J.

one who has investigated the stress-producing effects of actual modern engine loads on existing bridges that were designed for the Cooper loading, must be impressed with the lack of uniformity of stress throughout the various parts of the structure. This has resulted in wasted metal in some parts and insufficient section in others, the differences assuming a magnitude beyond the E-50 class, which makes imperative some changes in loading specifications to fit modern practice.

It is evident that train loads and locomotive loads do not vary in the same ratio. Train loads in general use are fairly well fixed, owing to the interchange of cars, so that comparatively unimportant branch lines and secondary railroads, with light motive power, will be subjected to the same train loading as the main lines with their heavy power. At present, train loads do not exceed 6 000 lb. per lin. ft. of single track, except in a few instances which will not affect the conclusions reached. Furthermore, the present design of cars must be changed so radically, in order to increase this train loading, that it seems as if this uniform load would represent a maximum train loading for an indefinite period.

Locomotive loadings do vary greatly on different roads and on the several sections of the same road, and necessarily so for economic reasons. Therefore, it is inconsistent that locomotive and train loads should be considered to vary proportionately. Mr. Steinman has gone a long way toward adjusting this incongruity. He has also produced a simple specification requiring a minimum amount of work in computation.

Good bridges can be designed for a uniform load plus spot loads, as suggested in Mr. Steinman's second series. This method is not new, but it has been presented in this paper more comprehensively than ever before. The selection and spacing of spot loads can be adjusted to suit the loading requirements of various railroads, resulting in more economical bridges. From its simplicity and its adaptability to various conditions, the second loading method is especially attractive.

HERBERT C. KEITH,* M. AM. SOC. C. E.—The author is to be congratulated on his paper; but bridge engineers are more to be congratulated on his having presented to them in this paper the results of his studies.

In 1882, under the direction of the late Samuel E. Tinkham, M. Am. Soc. C. E., the New York and New England Railroad Company adopted bridge specifications with a live load headed by a consolidation locomotive—a new type at that time—with a driving wheel load of 24 000 lb. per axle, or 96 000 lb. total weight on the drivers. A short time afterward, Mr. Tinkham thought it advisable to increase the engine load to 25 000 lb. per driving axle, or 100 000 lb. on all the drivers.

When it is noted that one of the engines mentioned by the author has a load of 300 000 lb. on the drivers, and another has an axle load of 78 000 lb., it is amusing to one who remembers the criticisms that were made at the time Mr. Tinkham and the New York and New England Railroad Company saw

* Cons. Engr., New York City.

fit to increase the weight on the drivers, in their specifications, to 25 000 lb. per axle and 100 000 lb. total driver load. At that time, many railroad men said that such a heavy engine would never be built; and as the New York and New England Railroad Company was not very prosperous in those days, it seemed somewhat ridiculous to them that such a poverty-stricken railroad, should use such heavy loads. Within three years that road had engines in use heavier than those that had been considered as excessive. The changes of the future cannot always be foreseen. There have been periods when the weights of locomotives have increased, and these periods have been followed by a slackening in the rate of increase of locomotive loads, during which the weights of cars have been increased, as when the large high-sided coal cars came into use, until now an equivalent to 6 000 lb. per ft. is a commonly accepted train load.

A few years after Mr. Tinkham left the New York and New England Railroad Company, a serious accident occurred near Boston, Mass.—Bussey Bridge collapsed under the weight of a train. This accident caused an investigation to be made by the company of the condition and capacity of its bridges, and the speaker was appointed to that task. He first studied the various engines used on the road, especially the heaviest of each type; there were Consolidation engines, Moguls, and the American type with only two driving axles. It was found that in bridges carrying all these engines, the maximum stresses in different members was caused by different types of engines; that is, one member might receive its maximum stress from a Consolidation engine, whereas some other member would be stressed more by a Mogul or an American engine. In some cases a member would receive its maximum stress from a lighter, but more compact, engine, than from the heavier, but longer, engine of the same type. It would have been quite a task to make calculations for all the bridges for all these locomotives; therefore, after some study, it was decided to use as a basic load for this investigation, a uniform load of 4 000 lb. per lin. ft., which was the recognized heavy train load at that time, with an excess load of 3 000 lb. per lin. ft. for a length of 25 ft. For the purpose of comparing the effect of the different locomotives, tables were prepared, that gave, for different lengths of span and different positions in the span, the relative moments and shears of various heavy locomotives that were used on different parts of the road, as compared with the basic loading of 4 000 lb. per lin. ft., with an excess load of 3 000 lb. per ft. for a length of 25 ft. This loading was adopted also as the standard for the design of new bridges on the road until the New York and New England Railroad Company was absorbed by the New York, New Haven, and Hartford Railroad Company.

It is interesting to note, however, and it is considered to be worthy of serious thought in connection with the model loading which Mr. Steinman has suggested, that although the heaviest locomotives may not run on the minor branch lines, there may be short trains of heavy cars hauled by a lighter locomotive on those lines. Instead of increasing, as was suggested, from the M-60 to the M-75 or the M-90 loading, it might be advisable to take cognizance of the fact that, on the branch lines, light locomotives may haul trains

made up of cars as heavy as those on the main lines with their longer trains and heavier locomotives. This matter should receive careful consideration.

PHILIP GEORGE LANG, JR.,* M. AM. SOC. C. E. (by letter).—For more than a generation the Cooper loadings have represented to American engineers the accepted medium for determining and recording the carrying capacities of bridges. A careful perusal of Mr. Steinman's paper indicates that it is primarily an attack on the Cooper system of loading. Certain particularly heavy engines in actual use have been selected, and an attempt has been made to develop a loading to represent the composite of these engines. The actual engines selected are extreme, and are used in special localities for special purposes.

Why such a special engine loading as M-60 should be followed by a train load of 6 000 lb. per lin. ft., is not apparent. As special engines were selected for study and comparison, there is no reason why similar cars should not likewise have been selected. Cars are in use on American railroads, that average 8 300 lb. per lin. ft. of track, and others have been proposed of more than 10 500 lb. per lin. ft. The Cooper loading provides for an increase in the following train load and thus tends to bring the average train load up to that of the engine load. The M-60 loading perpetuates a material difference in the effect of the engine and the train load on bridge structures.

The author states that "since the days of the E-40 loading, the axle concentrations have increased 100%, whereas the weight of train per linear foot has increased barely 50 per cent."

It would seem that such a statement is open to question. Although, perhaps, the engine axle concentrations have increased 100%, the weight of the train load per linear foot has increased about in the same proportion; certainly, 30 years ago, cars having capacities of 20 and 30 tons were common; to-day, cars with capacities of 55 and 70 tons are in general use, and many cars with capacities of 100, 110, and 120 tons are in operation and proposed for general use.

Again, the author states that "it [the new loading] should be from 25 to 50% heavier than the average present loading." Just what is meant by this statement is not readily discerned. The engines investigated by the author have an effect on bridge structures approximately equivalent to Cooper's E-73, which is equivalent to the M-60 loading, with the exception that the author's loading provides for a train load of 6 000 lb. per lin. ft., whereas, Cooper loading provides for a train load of 7 300 lb. per lin. ft., which more nearly approximates present-day equipment and rolling stock.

The simplified loading and the load formula are essentially an M-60 loading. Each of these forms is merely a return to the old and, perhaps, original idea of simplified loading to be used in order to make for ease in calculation. Such a loading has no basis in fact, and is simply prepared with the idea of making it produce stresses in bridge structures approximately equivalent to the motive power and rolling stock in use, or, in this case, approximately equivalent to the proposed typical engine designated as "M-60". There does not seem to be

* Engr. of Bridges, B. & O. R. R., Baltimore, Md.

any valid reason for the use of such a so-called "simplified" form of loading, and when a typical loading for the design and re-calculation or the rating of bridges in service is determined, a complete set of moment, shear, and floor-beam reaction tables may be prepared. Such tables for the Cooper loadings have been in use for many years and simplify the calculations; certainly, as much so as the proposed simplified loading, or the load formula.

It will be shown that the loading proposed by Mr. Steinman does not vary appreciably from the Cooper system of loading, and that the Cooper system represents the actual loads in service more nearly than the proposed M-60 loading.

In Table 10 is given the moments and shears for span lengths varying from 10 to 300 ft. The equivalent uniform load is shown for the E-60 and the M-60 loadings and also the actual E-rating for M-60 and the E-rating for M-60 as given by Mr. Steinman. The E-ratings given in the paper differ from those computed by the writer. For moments, with the span lengths shown, this difference ranges from 0.6% to 14.2%, with an average of 3.1%, and for shears from 2.4 to 7.4% for span lengths varying from 10 to 80 ft., with an average of 5.25 per cent. It would seem that this constitutes a rather remarkable variation where an effort is made to supersede the existing Cooper loadings.

Note.—E-60 = two of Cooper's E-60 engines, followed by 6 000 lb. per ft., or two 75 000-lb. axle loads, 7 ft., center to center.

The statement has been made that "the proposed loading has much to recommend it, particularly as applied to design. It more nearly represents future developments in train load to be expected in this country, and insures a more uniform design of bridges."

It is doubtful whether such is the fact. The M-60 loading approximates the heaviest engines now in use, but is followed by a train load of 6 000 lb. per lin. ft. of track, which does not represent present-day maximum train loads.

There is, therefore, too great a disparity between the engine and the following load in the case of the M-60 loading. This disparity does not exist with the Cooper loading, particularly when M-60 and the present loadings are compared with Cooper's E-73.

Fig. 17 shows moments and shears for existing heavy engines and the three forms of the author's proposed loading in comparison with Cooper's E-73. The stress-producing effects of the heavy locomotives approach Cooper's E-73 for the longer spans if the following train load is increased. It may also be noted that the actual engines are represented more nearly by the Cooper E-73 than by the M-60 loading. For moments, the variation of the actual heavy locomotives from E-73 is from 4 to 13%, whereas, for M-60, the variation is from 6 to 16 per cent. For shears, the variation of the actual engines is from 1 to 12%, whereas, for the M-60, it is from 4 to 12 per cent.

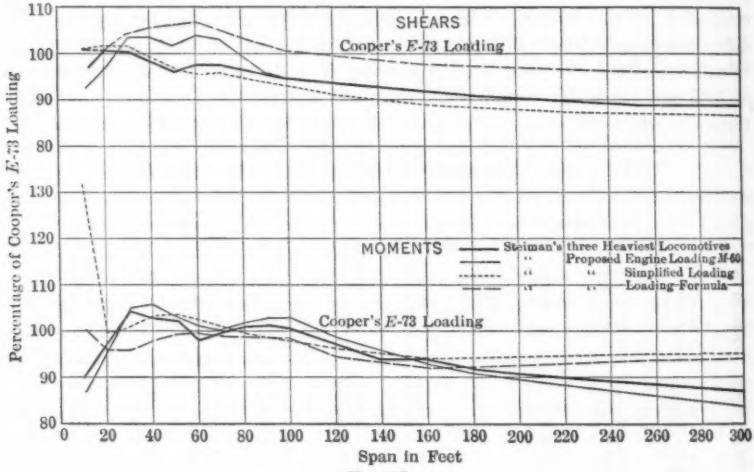

FIG. 17.

The further statement has also been made:

"In view of the present universal use of the Cooper loading, it may well be continued for the classification of old structures, in spite of some of the shortcomings pointed out by Mr. Steinman, but there is clearly need for something other than the short Consolidation locomotives of the Cooper series when it comes to proportioning the parts of a new bridge."

Evidently, it is proposed to use one method or system for the design of new structures, and to continue in use a different system for the rating of existing structures and for the determination of their carrying capacity. This would require a structure to be re-calculated for the other system. The bridges now in service cannot be re-calculated for a new system of loading. The work involved is too great, and engineers in charge of railroad bridges have not the time to change the records. Statistics indicate that there are about 250 000 bridges in use on American railroads. Presumably, complete records and calculations for these bridges exist.

In a study of the length of bridge spans, more than 5 000 railroad bridges have been classified, this study being representative of general bridge conditions in the United States. Exclusive of timber trestles, it was found that these bridges might be classified as to spans, as follows:

Less than 120 ft.	96%
From 120 to 149 ft.	1½%
" 150 to 199 ft.	1%
" 200 to 249 ft.	1%
" 250 to 300 ft.	4 spans
More than 300 ft.	11 spans.

It is apparent from the foregoing tabulation that the plate girder is the most prevalent type of bridge. Spans in excess of 120 ft. are relatively few, and, undoubtedly, the few bridges that exceed 300 ft. in length, when designed and built, are the subject of special consideration. The 1920 A. R. E. A. Specifications for Steel Railway Bridges treats of spans up to 300 ft. in length. In view of the classification of bridges mentioned previously, this discussion has been limited to the consideration of spans of less than 300 ft. Fig. 17 shows that for spans from 10 to 120 ft., there is practically no variation between the Cooper series of loadings, the engines in use, and the author's proposed loadings—certainly not sufficient variation to justify the adoption of a new system of loading.

In this connection, not only structures to be designed in the future must be considered, but also the vast number of existing structures in use, for which elaborate records are maintained in order that motive power may be assigned so as to secure the maximum benefits, considering the ultimate carrying capacity of the structures.

The author's study is appreciated, particularly as it has the effect of drawing attention to the question of the load to be used in the design of railroad bridges. Except for the advantage to be derived from such discussion, it is not felt that a convincing argument for discarding the Cooper system has been developed.

H. T. Welty,* M. Am. Soc. C. E. (by letter).—The author is to be complimented for his valuable contribution to this subject, which, in the writer's opinion, constitutes a strong argument in favor of retaining the Cooper system of loading, with possibly a modification in the uniform load following the series of wheel loads.

Many diagrams are shown, which will be of great value for reference, but to the writer, the most illuminating data are those given in Table 2 showing equivalent Cooper ratings for various spans of the proposed composite loading, M-60. The majority of railroad bridges have span lengths of less than 100 ft. It will be seen by referring to Table 2 that the moments produced by the M-60 loading for such spans are equivalent to Cooper's E-73 for spans of 20, 50, 80, 90, and 100 ft., and vary, for the others, from E-73 by less than 3 per cent.

Even for spans up to 160 ft., the variation is only 7%, and this is because Mr. Steinman uses a uniform load of 6 000 lb. per lin. ft. for his M-60 loading,

* Engr. of Structures, N. Y. C. R. R., New York City.

whereas, the Cooper E-73 would carry with it a uniform load of 7 300 lb. per lin. ft. Should the Cooper loading be modified to the extent of using 6 000 lb., which would be necessary to obtain a correct comparison with Mr. Steinman's M-60 loading, the agreement between the two would be still more striking, as this would raise the equivalent E-ratings for the longer span lengths. Also, for shear, the agreement is nearly as close, the Cooper loading giving slightly higher shear stresses.

The author takes a 140-ft. span as an example to show the deficiencies of the Cooper loading. He shows that, in the members of such a span, the Cooper loading would give stresses varying by as much as 37% from those produced by the N-1-S engines of the Pennsylvania Railroad Company. Such variations will always be found, some greater, some less, where actual locomotives are compared with a conventional set of wheel loadings, whether such loadings are the Cooper or the proposed M-60 loading.

The Cooper E-loading was adopted for the A. R. E. A. 1920 Specifications for Steel Railway Bridges, after thorough discussion and consideration. Some of the reasons in favor of the retention of this loading have been given in a paper* by Mr. W. S. Bouton and the writer.

The writer can see nothing of practical value to be gained and much to be lost by changing from the Cooper to the proposed M-60 loading, or to any other loading yet devised.

CLEMENT C. WILLIAMS,† M. AM. SOC. C. E. (by letter.)—This able paper is a valuable contribution to the science of structural design and should promote economy, adequacy, and consistency in the design of railway bridges. Although the Cooper loadings were a boon to structural engineering in one sense, they have been a detriment in another, inasmuch as they have caused the Profession to be so satisfied with a good device as not to seek a better one.

The writer in classifying many existing railroad bridges according to the Cooper loadings has observed the inconsistency of design required by that system. Mr. Steinman's statement that an error of 20 to 37% results from expressing modern loadings in terms of the Cooper engines does not indicate the seriousness of the lack of balance in most designs, for to find a structure the chords of which would class as E-50 and the web or floor of which would class as about E-25 is common, notwithstanding that the structure is fairly satisfactory as to actual requirements.

The Consolidation type of locomotive will probably never again be the prevailing type and, therefore, it represents, in its close concentration of load, a system of loadings different from those to which railway bridges will be subjected. Hence, there seems to be little excuse for continuing the inconsistent designs which result from this antiquated conventional loading. In fact, as long as it is continued, it will be common practice to remove old bridges because some of the main members and details are inadequate, while much of the structure is amply strong to carry the heavier loads to which it is subjected.

---

* Am. Ry. Eng. Assoc. *Bulletin No. 219*, September, 1919.

† Prof. of Civ. Eng. and Head of Dept., Univ. of Illinois, Urbana, Ill.

The Cooper system of loading has demonstrated the advantages of a conventional system of wheel loads as a basis of design for railway bridges, and probably the present need is a revision of the system rather than a radical departure in the type of loading.

The results obtained by the Special Committee on Stresses in Railroad Track reveal the effect of wheel concentrations in a new light and seem to call for accentuating this effect rather than minifying its importance by the use of equivalent uniform loads. Unless locomotive equalizers can be improved, it might be desirable to break the uniformity of axle loads and ascribe additional load to the main driving axle. In the writer's opinion, economy of design will be hindered rather than enhanced by the adoption of such an equivalent uniform load as that which the author proposes.

It is doubtful, however, whether a single system of wheel concentrations can be adopted, which will meet the varying needs. Many cantilever structures for carrying locomotives must be designed, for which close concentrations of wheel loads lead to grossly inaccurate results; therefore, the needs seem to require several different types of wheel concentrations, to be applied according to the anticipated development of locomotives as demanded by the topography and traffic conditions of the contiguous districts. One of these types certainly should be similar to that represented by the author's M-series, and the other extreme should be one of about two or three concentrations, as represented by the Atlantic type of locomotive, to be used especially for short spans, whereas, the third might be an intermediate type similar to the Cooper engines. The development of locomotives in recent years has shown the Mallet locomotive as the logical type for heavy loads and steep grades, hence, the design of structures on such roads should be predicated on a locomotive loading of this type. The demands of topography and of traffic in so far as they affect locomotive types can be predicted with a fair degree of reliability and bridges should be designed accordingly.

Attention should be called to the desirability of considering the entire problem of loads and stresses together rather than separately. The question of loadings to be used is not more than half the case, for many of the present and past inconsistent or unbalanced designs are due to illogical selections of unit stresses quite as much as to illogical schemes of loading. Every one knows that 16 000 lb. per sq. in. does not represent the limiting safe working stress in steel in direct tension. There is little uncertainty about the strength of materials; the uncertainty lies in the loads to which the structure is subjected. The logic of the situation, therefore, would demand that the factor of safety be inserted in the loadings rather than in the unit stresses. This arrangement would make a consistent design as between dead and live load, which is not obtainable under most existing specifications. Indeed, this illogical situation permeates nearly all structural steel design—buildings as well as bridges. Specifications governing reinforced concrete design are decidedly in advance of those for steel in this respect.

Mr. Steinman has opened an important question and has made a valuable contribution, but the writer would urge that the entire question of loads and

stresses be considered together, because a simple change from the E-series to an M-series is not likely to afford a permanent improvement. When a custom or device has become so ingrained in the education of engineers through years of use as the Cooper loading, considerable professional inertia is to be expected when an improvement is proposed. It is to be hoped, however, that the author's valuable contribution will lead to the introduction of a system of loadings and stresses that will yield a more consistent and economical design for railway bridges.

JONATHAN JONES,* M. AM. SOC. C. E. (by letter).—The following assumptions underlie the author's method:

(1).—On any important railroad, the structures should be designed for the typical rolling stock of that or any other railroad, with a consistent factor of safety, rather than for the typical rolling stock of the home road, with a consistent factor of safety, but subject to certain over-stresses from rolling stock of other types.

(2).—As locomotive weights increase hereafter, they are likely to increase by the retention of present types and wheel spacings, with a proportionate increase of each wheel load.

(3).—There is an advantage to be derived from having a uniform loading specification throughout the country.

If these assumptions hold, the author's work is so searching and instructive that it becomes authoritative, and his recommendations deserve to be put into force.

These were Cooper's assumptions also, and that they have not generally held is indicated by the number of railroads which use something other than the Cooper loadings, also by the discrepancies, pointed out by the author, between the heavy Cooper system and present-day developments.

Are the assumptions of to-day, then, better than former ones? The writer hopes that they will be thoroughly discussed by mechanical engineers; certainly, the whole matter must be referred to the American Railway Engineering Association before these assumptions can be disposed of.

Regarding Assumption (1), if the only negative argument was the present-day distinctions of railroad ownership, management, and design, one could foresee these distinctions breaking down, and rolling stock traveling promiscuously as it did during the World War. However, in locomotive types are there not districts, and, therefore, groups of railroads, which always will be well served by one type and poorly by another; so that if extra metal was placed in a certain truss member to accommodate this latter type at the normal unit stress, money would have been spent, that might well have been saved.

Regarding Assumption (2), will the development of electric traction introduce a type so different as to re-determine some of the author's maximums? Or, if the present types remain as the normal types, will they grow by mere proportionate increase in weight, or must not the wheel-bases increase? Will weight per foot of train increase in proportion to locomotive weights? It

* Res. Mgr., McClintic-Marshall Products Co., Pittsburgh, Pa.

seems to the writer that before any given railroad, well satisfied with the correspondence between its present designing stresses and the author's M-50, should specify M-50 plus an allowance for 50% overload, it might properly assume its present locomotive type, expanded both in weight and in dimensions, and compare the future stresses, thus calculated, with M-75 before accepting the latter.

With Assumption (3), the writer is in accord. Each step in bridge design from the preliminary estimate to the finished details would be simplified, cheapened, and increased in accuracy through the building up of standards of comparison, if more railroads would yield their special loadings and agree to a common standard. Therefore, the writer hopes that, even though the permanency of a new standard adopted to-day, may be voted dubious, one may be adopted, if only as a second step toward the ultimate—provided there is a pledge of adoption by sufficient additional railroads and an assurance of its persisting for, say, two decades more.

For the purposes of such a transition, a wheel-load diagram would be the least radical and the most acceptable. It is regrettable that the proposed M-type differs from any existing type in the change of driver spacing and driver weight in the two groups. This will make it difficult to "sell" the type to literal minded executives whose reactions will be that it is like neither their own engines nor those of any other railroad, and, therefore, cannot be reasonable. The logical answer to this is found in the author's derivation of the type. In addition to the advantages listed by the author, a diagram has the advantage, as a transition step, that it is a picture which invites review as mechanical developments come. The excess concentrations, or the formula proposed, if once adopted, lose all significance, except that they get a certain mathematical result. They are stopping, not starting, points in the reasoning, and until engineers are agreed that the starting point is beyond further revision, they should not bury it in a formula, but keep it out where everybody can look at it. This latter refers to the choice for publishing in a specification. The designer, however, would probably forget the wheel-load picture, paste Fig. 2 or Plate X in his handbook, and perhaps memorize Formula (4) for emergencies, feeling more than a little grateful to the author for precious hours of computation saved him thereafter.

GLENN B. WOODRUFF,* M. AM. SOC. C. E. (by letter).—The author deserves the thanks of the Profession for the study he has given to this subject.

The Cooper system of loadings does not fit present-day conditions, and this divergence is likely to be increased by future developments in engine and train loadings. However, the Cooper system is in general use, and, before making a change, it would be well to take all possible measures in order that the changed loading will meet the developments of the next thirty years as well as the Cooper loading has done in the past. A thorough study of present and probable future developments of motive power and equipment design should be made by the proper committees of the Society and of the American Railway Engineering Association.

* Asst. to Bridge Engr., Lehigh Val. R. R. Co., Bethlehem, Pa.

In considering the engines selected by the author as a basis for his "composite loading", the following suggestions are offered:

1.—One of the locomotives shown was built for pusher service and moves only over a limited part of the owning railroad. Others were built for roads having peculiar operating conditions. It is a question whether such locomotives are likely to come into general use.

2.—Engine No. 3 is probably somewhat ahead of its time, considering the present trend of locomotive loadings. The writer believes that the "composite loading" does not provide for short spans as it should and suggests adding a hypothetical engine of the Pacific type with axle loads of about 84 000 lb. on drivers. This would necessitate modifying the M-loading by specifying an alternate loading that would govern for short spans.

3.—Although the uniform load of 6 000 lb. may represent present-day conditions, the writer believes that it is not enough to be in keeping with the locomotives shown. There is probably more chance for a large increase in the train load than in the engine load. The writer would suggest an increase of about 10% in the train load of the proposed M-loading.

Considering the three alternate solutions proposed by the author, the writer prefers the continued use of the wheel loads. The saving of labor by the "simplified" methods is slight. By the use of tables and diagrams, the calculation of live load stresses is an easy task. It is a simple matter to prepare influence lines for any structure and then use the values given on Plate X. Having a set of concentrated loads in mind, one is less likely to err when it is necessary to give a hurried ruling on the acceptance or refusal of a heavy shipment.

The divergence between the "simplified" loadings and the "composite loadings" is nearly as great as between the composite loadings and the Cooper E-65. The writer fails to see any valid argument in favor of their use. Instead of designing for the M-60 loading, with a provision for 25% overload, the writer suggests designing directly for M-75, both for simplicity and economy. For economy of metal, it is desirable that all members should reach their limit under the same load, and the logical method of securing this result is by designing for ultimate load.

T. Kennard Thomson,* M. Am. Soc. C. E. (by letter).—The author deserves the thanks of the Society and the Profession for his valuable contribution on engine loadings. The writer recalls the unnecessary labor due to the great variation of loads, not only as specified by different roads, but also as adopted by individual roads. When he began working for a bridge company about thirty-six years ago, the entire design of bridges was in the transition period. Not only did each railroad have its own engine diagrams, but it also had its own peculiarity of design. Designs were so different that a glance would enable one to tell the railroad for which a shop plan was being made. The same applied to the bridge companies, as one would know, in most cases, on seeing a completed bridge, what company had built it.

* Cons. Engr., New York City.

In the intervening years, however, the railroads and the bridge companies have adopted the better and have discarded the poorer features, so that there is now much more uniformity. Probably no single feature has changed more than the engine and train loads. The efforts of each railroad to design its bridges as close as possible to one or two types of engines, has been, in many cases, false economy.

If Mr. Steinman's valuable paper causes the adoption of a few standard engine load diagrams, much mechanical labor in estimating will be saved, and the result will probably be fewer errors, more uniformity of design, and much less likelihood of frequent replacement.

As engineers, other officials, and even owners of railroads are changed so often, and as the same freight transfers from one road to another, it seems absurd to have such an infinite variety of engine loads adopted, only to be superseded by others in a few years.

The late Theodore Cooper, M. Am. Soc. C. E., was probably the first to devise an engine diagram which was generally adopted. The highway bridge companies often simplified matters by specifying a uniform load, plus a concentrated load, which saved much labor.

The writer hopes that Mr. Steinman's paper will result in the adoption of a few standard systems of loading, which will be tabulated for a uniform load per linear foot, and that these loadings will include long-span bridges for highway, combined highway, and railway purposes.

C. R. Young,* Assoc. M. Am. Soc. C. E. (by letter).—The author is to be congratulated for the service he has rendered the Engineering Profession in placing before it, data so convincing as to leave no other course open than to revise the present obsolete locomotive loadings. Much discussion has been given, in recent years, to the alleged inapplicability of the Cooper system of conventional loadings, but in most cases this has been of a desultory and general character. The author has established that, for heavy loadings on first-class railway systems, the Cooper system is inadequate and that the new proposed system would give safe and logical results. It now remains for the railway systems to make the next move. It is to be hoped that this will not be long delayed, and that, in particular, the American Railway Engineering Association will reconsider its decision to abide by the Cooper system.

Caution is needed in attempting to apply the author's proposed system of loading to railways carrying only moderately heavy traffic. Although his loadings are admirably suited to the heavier lines operating with steam locomotives, they are not so closely applicable to average or second-class lines on which existing locomotives, and those likely to be used for some years to come, are of a type distinctly different from those used by Mr. Steinman in the establishment of his composite loading. For this reason, it may be preferable to retain on some railways a loading system that more closely approximates the actual loadings in use than any class of the author's standard loading. The electric locomotive is becoming important and should be considered in any system that is devised to be used for a long time.

* Assoc. Prof. of Structural Eng., Univ. of Toronto, Toronto, Ont., Canada.

Of the three types of loading proposed, the writer prefers the loading formula. As each of these loadings is empirical, there seems to be no good reason to halt part way in the determination of stresses in bridge structures. Rather than adopt a loading that is conventional, it would seem best directly to adopt stresses that are conventional. There is no greater offense in the second method than in the first. It may be desirable to retain the wheel loading for investigation of special parts of structures receiving their maximum stresses under short loading, but, in most cases, the writer believes a distinct advantage would be derived from proceeding directly to the use of the loading formula.

EDWARD GODFREY,* M. AM. SOC. C. E. (by letter).—The author's able paper clearly demonstrates that, for the heaviest type of locomotive, coupled to the heaviest loads usually carried, the Cooper loading does not give consistent stresses nor economic design. This is, however, not a conclusive reason for discarding the Cooper standard of loading. If all bridges could be rebuilt, it would be desirable to establish a standard of loading to correspond with the latest in modern engine construction. Bridge specifications, however, are used largely to judge the capacity of existing bridges as well as a standard by which to build new ones. Furthermore, perhaps, a large mileage of the railroads in the United States will never be called on to carry the very heavy engine loads that are in use on a few of the roads. It would mean the rebuilding of many bridges and even the laying of heavier rails to enable these roads to carry heavy loads. As a criterion for judging the bridges on such roads or the building of new ones, these heavy loads, therefore, are just as inappropriate as the Cooper loading is on roads where the modern heavy engines are in use.

It is difficult to discard a system of calculating stresses that is as interwoven with railroad bridge design as the Cooper standard loading. By using two simple modifications of the Cooper standard of loading the author's principal objections can be overcome, and it can be made to give results as nearly equivalent to the modern heavy loading as practical considerations demand.

One modification is to use heavier axle loads in the pair of concentrations for stringers or short girder spans. The other modification is to use a train load less than that called for by the class of engine in the standard. For example, let an E-70 engine be followed by 6 000 lb. per ft. instead of 7 000 lb. per ft. By a simple rule such as this, the lack of economy in long spans is eliminated.

After a standard of design is once established, it should be adhered to with little or no departure. One can believe this and still be aware of the fact that the exact stresses computed may never be even closely approximated in the bridge. The ends of safety and stability are served, and this is the principal object. The main reason for rigid adherence to certain rules in calculating stresses is to have a definite standard of design. In competitive

* Structural Engr. (Robert W. Hunt & Co.), Pittsburgh, Pa.

design, this is particularly useful, as without a definite standard, comparisons could not be made. It is not so necessary, therefore, whether a diagram of loading agrees exactly with the axle loads of a locomotive, as long as the heavy concentrations in the diagram practically agree with those to be used, or as long, in fact, as the load per foot is almost the same.

The only bridge loading for calculating stresses that can be tolerated by designers is either a uniform load, a system of concentrations, or a combination of both. To introduce a new system of concentrated loads would place a great burden on designers who are familiar with the Cooper loading and have many tables, etc., based on it.

It would not be wise to mask bridge loading by a formula, as proposed by Mr. Steinman. The general manager of the railroad will say, "never mind the formula, what kind of engine and train loading can I run over this bridge?"

To try to interpret the strength of an old bridge, or a new one for light loads (and such will be built for many years to come), with respect to the heavy Mallet type of loading, would be just as awkward as it is to interpret the strength of a heavy bridge by the use of the Cooper loading.

The Cooper loading standard is needed and can be used for many years to come, and with slight modifications it can be made to suit any modified locomotive loading with all the accuracy that actual conditions demand.

A. F. Robinson,* M. Am. Soc. C. E. (by letter).—The author has condemned the E-loadings and submitted a new loading. In the writer's judgment, the Cooper loading is superior in every way to that proposed by the author. The simple statement in the paper that the Cooper loading is out of date does not necessarily make it so. The author has submitted nothing whatever, except this bare statement.

Before adopting the Cooper E-loading, when making up the A. R. E. A. Specifications of 1920, Committee 15 of that organization studied the question with extreme care. A sub-committee submitted a report which showed that the moments and shears for the E-series loadings compared with those for all the heavy engine loadings.

In the writer's opinion, it is not necessary to try to make up an ideal engine loading which shall consider in any way the Mallet type of locomotive, as it will not be necessary to provide for many engines of that type. Experience has demonstrated that the large Santa Fé type and the Mikado type of locomotives will give much better net returns in service than any of the Mallet types. This being the case, there is no need of providing especially for the Mallet engines. As locomotive designing progresses, it may be necessary to modify or re-construct the E-loadings, but it is not necessary for the present and the immediate future. A careful study of the report of Committee 15 of the American Railway Engineering Association, submitted with the 1920 Specifications of that organization, will clearly demonstrate what the writer has stated.

The E-loadings follow very closely the weights, moments, and shears, as given by the heavy power in service, which includes the Mallet type of engines.

* Bridge Engr. System, A. T. & S. F. Ry., Chicago, Ill.

This E-loading furnishes a unit or basis for comparison which has been generally adopted. The locomotive loading proposed by the author is in advance of anything that is likely to be used on the Atchison, Topeka and Santa Fé Railway for many years to come. An engine loading that is materially in advance of the engines that are being used at the time, should not be adopted.

Although the E-loading can be criticized in many ways, it still meets present-day requirements very well and is much to be preferred to the loading submitted by the author. The M-60 loading does not give any check on the effects of the motive power now in service. Before this system of loading is generally adopted, the locomotives must be increased materially in weight and a different kind of a road-bed, together with much heavier rails, will be necessary. The writer is in favor of adhering to the E-loadings. This is a case where the cure is much worse than the disease.

Lewis E. Moore,* Assoc. M. Am. Soc. C. E. (by letter).—Some of the most difficult questions with which railroad bridge engineers have to contend are the probable future increases in loads and whether the useful life of a bridge will be ended before its capacity is exceeded. Engineers hardly could have been expected to foresee or to provide in their bridges for the tremendous increases which have taken place, both in the total weight of locomotives and in the wheel concentrations. To predict what will happen is difficult, but that is no argument for failing to make as wise provision for the future as circumstances and conditions seem to warrant.

For the heaviest present-day loading, the Cooper series does not meet the requirements. Perhaps, few railroad companies at present use locomotives like those on which Mr. Steinman's diagrams are based, nevertheless, the tendency of loads, both total and concentrated, has been upward for a number of years. Any change in loading which better meets the tendencies of locomotive design and which can be used as a more or less general "yard-stick", is an advance. The fact that all lines do not use such enormous locomotives as the maxima treated in the paper, is no reason for condemning the system evolved in it. It is possible to use any part of Mr. Steinman's loadings in any particular case. As to whether Loading Nos. 1, 2, or 3, is used would depend largely on the ideas of the individual engineer. Having the loading in such shape that one can check the resulting stresses by judgment to a certain extent, is, perhaps, to be preferred to a single loading formula, especially as difficulties of computation cannot be allowed to stand in the way of excellence or reasonable accuracy of design.

The omission of electric locomotives from the paper is rather unfortunate, because it seems probable that their use will increase materially in the future, particularly on congested lines with heavy traffic. To see just where the electric locomotive fits among the engines used by Mr. Steinman will be of interest. It would seem that the stress-producing effects of a proposed Norfolk and Western freight locomotive† having four axle loads of 70 250 lb. each, concentrated in a distance of 16 ft. 6 in., with another similar series of loads 22 ft. away, would be somewhere between those of Loadings Nos. 2 and 3, sug-

* Cons. Engr., Boston, Mass.

† *Engineering News-Record*, September 14, 1922, p. 437.

gested by the author. Accurate computation might not confirm this somewhat superficial conclusion.

The size of the engine governs the length of the train, but it does not govern the weight of the individual car. In most cases, any locomotive, however small, that a railroad possesses, is capable of pulling a train of maximum weight per foot, which will fill its longest bridge span, so that whatever variations are made in the locomotive loading, the loading following the tender should be kept to the maximum and should be the same whatever the type or weight of the locomotive. This should be so, irrespective of the location of the railroad, as long as it has trunk-line connections, and, also, of whether the bridge is on a main line or a branch.

The exact trend of locomotive development for the future is problematical, but owing to the present tremendous wheel concentrations and the resulting wear on road-bed and track, it would seem that the limit has been almost reached. This has been said in the past, and yet wheel concentrations have increased. The limits of clearance have now been quite well filled and as the cost of increased clearances is practically prohibitive, it is perhaps more reasonable to say that the limit of individual wheel concentrations has now been reached than it would have been some years ago. When the dimensions of width and height are entirely utilized, only length remains in which expansion can take place. It would seem, therefore, that locomotives may become longer in the future, with perhaps a different wheel arrangement.

Locomotive cylinders and reciprocating parts and rods have become so heavy that development may take place along entirely different and new lines. This might mean the substitution of a vertical high-speed engine of the marine type, probably condensing and compound, geared to the axles, instead of the present enormous pair of single cylinders. Such a construction should have a number of advantages toward the reduction of weight and possible increase in fuel economy, as well as a lower cost for repairs. Such construction would make it possible to install an engine on the tender and so use for tractive purposes a dead weight which must now be hauled with no compensating advantages. Development of this kind would probably result in wheel arrangements somewhat similar to that of the existing electric locomotives. Such locomotives, if properly designed, could be run in either direction with equal facility, thus obviating the use of turn-tables and the periodical increases in turntable lengths, which have been one of the many difficulties facing railroad engineering departments. The high-speed engines of the marine type could be made interchangeable so that if repairs were necessary to the engine and not to the boiler, the engine could be removed and another substituted in its place, which would make it unnecessary to tie up the whole expensive machine for repairs to, perhaps, a minor part. A locomotive of the type outlined could be made to have a torque practically as steady as that of the electric motor. The balancing of the engines would be much simplified and the wear and tear on the track and equipment, due to lack of balance, would be practically eliminated.

Railroad motive power executives, if confronted with this development, will say that Trevithick used a vertical cylinder locomotive and discarded it because of the vertical vibration. To those who may raise this objection, the writer will say that Trevithick's engine was not balanced and will also ask them to consider the automobile.

In the desire to prophesy a little, the writer has apparently wandered far from the main subject, but perhaps not so far as may appear. Such a development would result in locomotive loadings which would more closely approach the general characteristics of those given in the paper, although they would not necessarily have such large wheel concentrations. Mr. Steinman deserves great credit for his paper. The writer believes the paper to be progressive and that the system of loadings proposed by the author will be quite generally adopted.

CHARLES B. WING,* M. AM. SOC. C. E. (by letter).—The author has performed a valuable service in showing the discrepancies existing between stresses obtained by using the Cooper E-system of engine loadings and those caused by seven types of engines now in quite general use. Calculated static stresses in railroad bridge structures subjected to train loads serve two purposes: First, to form a judgment as to the safety of structures now in use; and, second, to form a basis for the design of structures yet to be built.

Engineers charged with the responsibility of maintaining existing structures stressed by new types of locomotives of increased weight, naturally choose the wheel-load method of analysis and for this purpose use the wheel concentrations and spacings belonging to the heaviest engine operating on the division on which the structure is located. In the writer's opinion, no system of engine excess or equivalent uniform load analysis is as satisfactory for this purpose as the method of using the actual wheel loads and spacings of the heaviest engine in operation.

As a basis for designing new structures, it is advisable to look forward to probable changes in engine loadings. If, as the author contends, the present standard Cooper E-system is no longer adequate, a new standard should be adopted. The author's proposed M-system of loadings is worthy of consideration and may prove to be the needed modification of the Cooper E-system.

The determination of the static stresses in the members of bridge trusses, due to a system of moving concentrated loads, is a comparatively simple problem of analysis.† Stresses thus obtained, properly modified for impact, form a safe and satisfactory basis for bridge design.

The writer can see no advantage to be gained by the adoption of either of the substitute systems mentioned by the author. The difficulties of wheel-load analysis mentioned by many writers in the past are more imaginary than real. Given a moment diagram and a fair knowledge of stress analysis, the time consumed by either of the proposed systems of analysis is approximately the same. As the proposed substitute systems are based on the actual wheel concentrations, there seems to be no good reason for their preference.

---

† "General Criterion for Position of Loads Causing Maximum Stress in Any Member of a Bridge Truss," by L. M. Hoskins, *Transactions*, Am. Soc. C. E., Vol. XLII (1899), p. 240.

R. O. STEWART,* ESQ. (by letter).—The author has chosen those few types of locomotives, which produce peak points on a moment curve, and has compiled a series of arbitrary loadings which will give approximately an enveloping moment curve for such peak points. There is nothing new or unusual about the two alternative methods of handling this arbitrary loading, and these alternatives do not require or merit special consideration, as the same principles can be applied to any conventional system of concentrated loadings.

The essential requirements of a standard bridge loading for any given railway are, as follows:

(*a*).—One standard system of conventional loading must be used for all bridge structures, such loading to be increased or decreased in fixed ratios for heavy or light structures. For purposes of design, this requirement is desirable and, for the classification of old structures, it is essential.

(*b*).—The basis of any standard bridge loading should be an average of the heaviest of the existing or probable locomotives in greatest common use on the railway, or, in other words, the standard loading should be designed to give the most economical structure possible for the class or strength of structure most generally required. The standard loading should also be such that proportional increases or reductions of it will produce the smaller number of heavier or lighter structures, without too great a sacrifice in economical design.

(*c*).—As the tendency has been (and may possibly continue to be) for the weight of rolling stock to increase slowly, the standard loading should tend to be more nearly normal to the heavier rather than to the lighter existing or probable locomotives.

On the basis of these requirements for a standard loading and considering not one railway, but the majority of American and Canadian railways (the customary types of locomotives being somewhat common to both countries), the writer would consider Mr. Steinman's proposed standard loading at fault in the following respects:

1.—Rather than being based on the heaviest of the regular standard types of locomotives in common use on the majority of average railways, the loading has been designed to cover only the unusually heavy locomotives among a few railways. These locomotives are probably operated only on restricted districts where special design provisions could readily be made for the particular heavy locomotives involved.

2.—Contrary to Mr. Steinman's contention, this loading cannot be reduced in fixed ratios, in a manner similar to the Cooper loading, to suit properly the requirements of railways operating only lighter locomotives or to suit the requirements of various intensities of loading necessary on different sections of any one road.

The author's M-60 is a fair loading for any railway operating locomotives of the Erie Railroad, Class P1, 2-8-8-8-2, the Virginian Railway, Class 2-10-10-2, and the Pennsylvania Railway, Class N-1-S, 2-10-2, the train load being 6 000 lb. per lin. ft. in each case. However, this is the one and only condition

* Asst. Engr. of Standards—Bridges, Canadian National Rys., Grand Trunk Pacific Ry., Toronto, Ont., Canada.

in which the use of this loading is fair or economical. For a railway operating only one or two of these heavy classes of locomotives, the author's loading is not correct.

Mr. Steinman states that "this loading can be increased or reduced in fixed ratios in the same manner as the Cooper system of loading". The bulk of the bridges of the Canadian National Railways are being designed to carry economically the Santa Fe T-1-c, Mikado S-1-e, Consol N-2-a, and Pacific J-7-c locomotives, and the writer thinks that these four classes of locomotives represent quite fairly the general loadings of the average Canadian and American railway. These locomotives do not fit the author's loading nearly as well as they do the Cooper loading, except possibly up to spans of 150 ft. In addition to this, the Canadian National Railways has a number of branch lines for which it is unlikely that any but the lighter locomotives will ever be required. The author's loading is at its worst for these light locomotives, whereas, the Cooper loading is at least a fair approximation, considering that the number of new bridges required for such loading is small compared with those required for the heavier locomotives.

The writer does not think that the Cooper system of loadings is perfect, or that it cannot be improved. Quite an extensive study of this matter was made in 1921, using the locomotives of the Canadian National Railways. Although several systems of loadings were devised, which were considerably more normal to the heaviest locomotives, than the Cooper system, it was decided that, at least for the present, the use of the Cooper system would give designs as economical as any other loading which could be evolved. Railways the requirements of which for bridge loading were heavier than those of the Grand Trunk Pacific Railway might find it advantageous to adopt a system more nearly normal to somewhat heavier locomotives than those to which the Cooper loading will agree, but the writer thinks that the author is altogether wrong in proposing as a general standard a loading based on a normal to the few exceptionally heavy locomotives which he has chosen as the "heaviest existing locomotives".

HENRY S. JACOBY,* M. AM. SOC. C. E. (by letter).—The author deserves much credit for the scientific manner in which he has investigated this subject, and the systematic form in which the paper is presented. The use of a composite standard loading and of the segments of the influence triangle for any truss member are especially noteworthy. The comparisons made between the results obtained for each of the seven heavy modern loadings that are selected for the composite standard and for the Cooper standard now in use, seem to answer most of the questions about their relationship, as far as static stresses are concerned.

The question may be raised, however, whether the proposed M-60 loading with its relatively lighter uniform train load will represent more closely the development of future actual live loads than the equivalent Cooper loading with its relatively heavier train load. This matter will require the composite judgment of a great number of railroad engineers in active practice.

* Prof., Bridge Eng. Emeritus, Cornell Univ., Bethlehem, Pa.

If the officers of any railroad on which light motive power is used, are in doubt whether locomotives of any of the types considered by the author are likely to be adopted on their line in the future, and who, therefore, would hesitate to accept a standard like M-40 or M-50, an independent investigation can readily be made to decide the question. The time required for such an investigation would be short in comparison with that devoted to this subject by the author. Only the heaviest locomotives of each class now in use on the given railroad need to be considered. The spans can be limited to those which include, say, 90% of the bridges now in use. A study of the results for these short spans will soon indicate whether greater or less differences among themselves in equivalent uniform loads are caused by those locomotives for any given section or truss member than by the seven locomotives selected by the author. After selecting the equivalent uniform loads from which a special composite standard for that railroad may be derived, they can be compared with those given by the author to see whether they differ materially from those obtained by scaling down the corresponding values due to the M-60 loading. It may also be observed whether the differences are larger for the web members or the chord members. For plate-girder spans, the moments and shears are due to the locomotives alone, except for the small number having the largest spans.

In making a choice of one of the three loadings proposed by the author, it is well to remember that locomotive wheel loads were introduced in the United States nearly fifty years ago, and that numerous discussions since that time have failed to displace them. It is illuminating to re-read the discussion* held at the Annual Convention of the Society on June 27, 1899. This is especially true with respect to forecasts made at that time regarding the increase of locomotive loads. Although a series of uniform loads determined by a formula may be more scientific, there are evident advantages in a series of wheel loads, which commend it to railroad officers outside the engineering department. With the aid of tables and diagrams, the computation of stresses is practically as simple in one case as in the other.

The fact that the American Railway Engineering Association concluded to retain the Cooper series of loading in its 1920 Specifications, after its Committee had carefully re-investigated the subject, makes it necessary to present exceptionally strong arguments to secure a change in the near future. The extensive records now in use on the rating of railroad bridges in terms of the Cooper series make it inadvisable to introduce a change involving so many short-span bridges, unless advantages are secured, which exceed in value that of the labor required.

CHARLES EVAN FOWLER,† M. AM. SOC. C. E.—A composite loading was first proposed before the Society in the speaker's paper entitled, "Revision of the Niagara Railway Arch Bridge."‡ The same general idea is being used by P. B. Motley, M. Am. Soc. C. E., on the Canadian Pacific Railway, by

* *Transactions*, Am. Soc. C. E., Vol. XLII (1899), p. 189.

† Cons. Engr., New York City.

‡ *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–20), p. 1919.

J. J. Yates, M. Am. Soc. C. E., on the Central Railroad of New Jersey, and by others.

When the speaker broached this subject to the Committee of the American Railway Engineering Association in 1919, he found the members of that Committee so strongly in favor of retaining the Cooper Class E-loading that the matter was not pressed, as that Committee represented the engineers who are responsible for railway loadings. Thus, it is certain that the Association and the Engineering Institute of Canada must be consulted and first be satisfied if any proposed loading is to be substituted for the Cooper system, even though that is so badly out of date and out of time with modern bridge engineering.

The history of bridge loadings shows that changes must come about slowly. The speaker recalls the wheel-load diagrams with resultant panel loads, published about 1885, by the late Thomas H. Johnson, M. Am. Soc. C. E., of the Pennsylvania Lines Southwest; the ones most used were two 74.5-ton engines followed by 32-ton cars, or about 1 640 lb. per lin. ft.; two 92.3-ton engines with the same following load; and, in 1888, the undreamed-of load of two 107.5-ton engines followed by 4 000 lb. per lin. ft. About this time, J. E. Greiner, M. Am. Soc. C. E., devised the plan of using a slide-rule of special construction for sliding the train along panel pointers to obtain moments and shears. Soon after, it was discovered that equivalent uniform load curves or tables could be calculated and practical accuracy obtained as great as that by the laborious use of wheel loads. The engineers of the Youngstown Bridge Company constructed such curves for the locomotives of about thirty of the railways for which bridges were being built and no errors resulted. This method has largely continued to the present time, and it is little trouble to shift to uniform load curves of some type of composite loading. What shall this be? Manifestly, if standard axle spacings and loads for the different types of locomotives could be adopted, the problem would be simplified and the standard adopted would be more lasting. This would cover Class A for Mallets; Class B for the Santa Fé type; Class C for Mikados; Class D for electric locomotives; Class E for the Cooper loadings, and Class F for the final or composite loading. Some of the road officials already have taken action in this direction and toward reducing counterbalancing, and the rapid change to electric operation being made on many roads will cause still further consideration. The slow speed of freight engines makes the effect of load plus impact no greater, perhaps, than that of high-speed passenger locomotives of lesser total weight. The heaviest locomotives are only used on a limited mileage, whereas, on branch lines, much lighter locomotives are used than on the main lines. The new Michigan Central Locomotive No. 8 000 will haul a train of 120 cars, but the car weights or train load per linear foot are no heavier, and doubtless seldom reach more than 4 000 lb. per lin. ft. This is one example of the fact that the train loads should be from 500 to 1 000 lb. per lin. ft. lighter for each Cooper loading after E-50 is passed. This and various other matters of loading are dis-

cussed in the speaker's paper on the Niagara Railway Arch Bridge.* Thus, the problem of devising a final composite loading is somewhat complex, and must only be done by all those interested.

CHARLES F. LOWETH,† PRESIDENT, AM. SOC. C. E.—The speaker is in sympathy with the quite general desire to simplify and, at the same time, to make more practical the typical engine and train loadings used for proportioning railroad bridges.

When he first began his experience in designing railroad bridges, it was the custom to ascertain the heaviest locomotive and train loading in use anywhere and utilize them in proportioning the design of the proposed structure. Now and then, something was added for possible increase in weight of locomotives and train loadings. This method involved a great deal of painstaking work and resulted not infrequently in the boast that the structure was designed for the heaviest locomotive known; but often before the bridge was completed, a heavier locomotive was built, with altogether different axle spacings, and all the painstaking efforts for perfection of design to meet actual conditions were defeated. The author's suggestion that railroad bridges should be proportioned for a typical uniform loading would be ideal, if one could be determined that would approximately fit actual conditions and would be generally accepted and used. Such a practice would be along the lines of that of the noted bridge designer, the late George S. Morison, Past-President, Am. Soc. C. E. His method was to take a uniform train load, headed by a largely increased loading for a length of one or, perhaps, two panels, in order to allow for the additional weight of the locomotive over that of the train. The application of this loading was simple and had many advantages, but it fell into disuse, because it did not approximate closely enough actual conditions, and, perhaps, equally on account of the fact, that the loadings then generally used did not provide sufficiently for the increasing weight of locomotives and cars.

The speaker remembers the frequent arguments in those early years as to whether locomotives would continue to be built materially heavier than the largest in use at the time. Each new locomotive seemed to be about the maximum that could be designed and would be practicable; yet, as the years passed, there was a continuing succession of heavier locomotives, and the end is not yet in sight. With heavier rails and better track construction throughout, stronger equipment, mechanical stokers, and other locomotive improvements, the increasing cost of transportation, and the necessity for the utmost economy in railroad operation, it is quite possible that locomotive and train loadings may continue to increase in weight.

However, railroad transportation is undergoing an evolution and the trend in the future may not be in the same directions as that in the past. The speaker thinks that it may be within the bounds of possibility that future transportation requirements may change, in some localities at least, to a demand for smaller train units, more quickly moved. This suggestion may

* *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–20), pp. 1925 to 1930, and p. 2020 *et seq.*

† Chf. Engr., C. M. & St. P. Ry., Chicago, Ill.

smack of heresy, because until the present time, it seems to have been a generally accepted rule that economical railroad transportation requires train units as large as can possibly be handled.

Another possibility to be taken into consideration is that of the electrification of steam railroads. As the financial problem involved in electrification is so great, the speaker does not expect to see the change from steam to electric power, for general railroad purposes, come about rapidly. There will be, however, a tendency in that direction. The electric locomotives are generally lighter in weight, at least when measured by units of length, and, what is perhaps even more important, they produce less impact effect on track and structures. They undoubtedly will be less frequently double-headed for heavy trains than steam locomotives. These considerations tend to reduce the justifiable weight of train loadings.

It would be desirable if locomotive loadings could be safely standardized without getting too far afield from the actual conditions to which the structure would be subjected. A steel bridge superstructure, for the most part, is permanently located. There are parts of railroads where the traffic requirements will never call for locomotives and train loadings as heavy as those now in general use. There are other parts where the traffic requirements will call for increasingly heavier train loadings. The speaker thinks that advantage of this difference in conditions is not as generally taken as it should be. He also questions whether sufficient consideration has been given the fact that the heaviest locomotives are those used in freight service which, from their design, as well as from their use, are limited to speeds much less than those of the lighter passenger locomotives. There are also other conditions which affect the speed of trains over any structure. Speed is a factor in the impact effect of the load, and to apply the impact for maximum speeds, irrespective of the structure and type of locomotive used, is not a rational method of design.

Relative to the effect of the electric locomotive on bridges on the Pacific Coast Extension of the Chicago, Milwaukee, and St. Paul Railroad, the speaker would explain that those bridges were designed before the decision as to electrification had been fully made. The bridges were proportioned for what is known as the Cooper E-55 loading. The electric locomotives in use, although among the heaviest, if not the heaviest, which have been built for any service, are well within the limits of the E-55 loading for which the bridges were designed. The electric locomotives have practically no unbalanced and reciprocating parts so that their impact effect on track and structures, as compared with steam locomotives, is small.

RALPH MODJESKI,* M. AM. SOC. C. E. (by letter).—There is no doubt, and it has been well brought out by the author, that the Cooper standard loading does not properly represent modern loading conditions. It would be impossible to construct a rating diagram which would correspond to the power as well as to the equipment of every railroad in the United States. It has long been recognized that the Cooper diagram cannot be strictly applied to all loadings,

* Cons. Engr., Chicago, Ill.

principally because, in individual cases, the maximum wheel concentrations have no fixed relation to the train loads. Therefore, instead of calculating a bridge for the Cooper standard loading, some combined loading would be taken, as, for instance, the Cooper E-60 locomotive followed by a train load of 5 000 lb. per ft. of track. A combined loading of this kind may be fitted quite closely to the motive power and to the train loads of any railway system. It has the advantage of allowing comparison between bridges constructed at different periods; their relative rating may then be determined without extra calculations and may be easily understood by the railroad executives.

If a new loading is adopted at this time, the comparison of the rating of existing bridges that were calculated on the basis of the Cooper loading, with the new bridges calculated by such loading, would be obliterated and could only be made by the use of tables or calculations, or both.

Referring to Table 2, it may be noted that the ratings for the center moments and end shears are quite consistent for spans up to about the length of two Cooper locomotives. Beyond that length the rating decreases, owing to the increasing influence of the uniform train load. For a 1 000-ft. span, the ratings are practically equal to the uniform train load of the Cooper E-60 loading as well as to that of the proposed M-60 loading, because the influence of the locomotive load becomes small. If, therefore, all spans from 10 ft. to 1 000 ft., were calculated for a load consisting of the Cooper E-73 locomotives followed by 6 000 lb. per ft. (calling such a load E-73-6 000 for convenience), the ratings of Table 2 would become uniform for all practical purposes and would closely correspond to the author's M-60 loading. Some slight discrepancies or even inconsistencies might occur, but this would also be the case with any other system of wheel loading. Considering that unit stresses are based only on good judgment and, further, that allowances must be made for impact, unbalanced wheels, wind, tractive forces, and secondary stresses, the difference between some such loading as E-73-6 000 and M-60, will be small indeed.

If a revision of loading is advisable, would it not be better to adopt at once different classes of loading based on a uniform load and one or more "floating" concentrations, such as those proposed by the author as a second alternative, rather than resort to another system of wheel loading which may again have to be revised in the near future. The writer believes that a uniform loading with one floating concentration would fill all requirements. Some large bridges in the United States have been calculated in such a manner.

C. A. P. Turner,* M. Am. Soc. C. E. (by letter).—As a railroad train passes over a bridge structure, a certain element of time is required to overcome the inertia of the mass in producing the greatest deflections of the parts and of the structure as a whole. The greatest elongation under tension, or deformation under compression, is a thermo-dynamic function such that the mechanical energy represented by the transfer of the kinetic heat energy of molecular vibration in the resisting metal to the potential energy of deformation of strain is double the external mechanical work of the load when the stress is tension, and the reverse when it is compression. This excess energy

* Cons. Engr., Minneapolis, Minn.

is radiated to the surrounding medium or the absorption of heat energy from it takes place. Accordingly, there is an instantaneous or kinetic deformation and a static deformation which involves the thermal effect.

The relative amount of energy involved, as shown by Kelvin's thermal dynamic theory, is approximately double that of the work of the external applied forces. The full development of the static deformation requires an element of time, which in connection with overcoming the inertia of the mass, may be approximately estimated at 1 sec.

If the train is traveling nearly 60 miles per hour, its speed may be taken at 100 ft. per sec., and the vertical impact on a member would approximate,

$$S\left(\frac{100}{A+100}\right)$$

in which,

S = live load stress; and

A = length of track loaded, for maximum effect, when the initial dead load stress equals zero.

However, if the member is under dead load stress, the approximate vertical impact strain would equal,

$$S\times\left(\frac{L}{D+L}\times\frac{100}{A+100}\right).$$

The rolling load tends to set up structural vibration laterally as well as vertically, and the total impact is the resultant of the vertical and horizontal effects combined. In the ordinary pin-connected bridge, with a train speed of about 60 miles or more per hour, the lateral impact may be assumed to be approximately equal to the vertical impact effect. Therefore, for the pin-connected railroad bridge, the formula for total impact is:

$$I=S\left(\frac{L}{D+L}\times\frac{140}{A+100}\right).$$

The stiffness of the riveted structure would reduce the necessary impact allowance to about

$$I'=S\left(\frac{L}{D+L}\times\frac{130}{A+100}\right).$$

The vertical effect of impact would vary approximately as the speed of the train, whereas, the lateral effect would vary roughly as the square of that speed. Accordingly, if the rational impact allowance of the high-speed passenger train is to be compared to that of the ordinary freight train, which travels about half as fast and the lateral impact of which would be one-fourth as great, these formulas would immediately reduce, for the pin-connected bridge, to

$$I=S\left(\frac{L}{D+L}\times\frac{55}{A+50}\right)$$

and corresponding values for the riveted bridge.

It accordingly appears that the value of the passenger train impact for a Cooper E-60 loading would be nearly equal to an E-75 loading for freight train speeds. As the excessive Mallet engines are not used for fast passenger traffic,

there is little call for a radical change in the present typical engine loading when coupled with a rational impact formula. The present standard furnishes a uniform method of comparing the capacity of bridges, and tables for its convenient application are in general use.

The fact that the Cooper loading approaches as closely to the wide range of engine loading as any that can be devised and, if used in conjunction with a rational impact formula, meets all requirements, argues against introducing other and different types of typical engine loadings, which would only add confusion to present methods of investigation. If the impact formulas are considered for range of stress from tension to compression, the first member in the foregoing suggested formula would become unity and may be disregarded.

Mr. Steinman's painstaking investigation is a distinct addition to the literature of the subject, but his showing when considered in connection with rational allowances for impact, does not indicate the need of any radical change in the well established Cooper loading.

D. B. STEINMAN,* M. AM. SOC. C. E. (by letter).—The writer gave his best efforts to the preparation of this paper and was agreeably surprised by its generous reception. The interest shown and the many expressions of appreciation have more than rewarded him for his work.

The paper was intended to be suggestive rather than final, to evoke discussion, to outline the questions at issue, and to indicate methods of analysis, solution, and application. The proposed loading specification, in its three different forms, was merely tentative, and was submitted to the members of the Society as a basis for discussion or modification. It is, therefore, most gratifying to the writer to see his labors rewarded by the endorsement of the Special Committee on Specifications for Bridge Design and Construction, of the Society, in its recommended specifications for steel railway bridges.†

The three forms of loading specification proposed in the paper may be designated as follows:

M-Loading No. 1—Typical engine diagram.
M-Loading No. 2—Simplified loading diagram.
M-Loading No. 3—Equivalent uniform loading formula.

The discussions disclosed varying preferences between these alternative loading specifications. The preponderance of choice appears to have been for M-Loading No. 1, the typical engine diagram. This also proved to be the choice of the Special Committee on Specifications for Bridge Design and Construction, which adopted M-Loading No. 1 (with a slight modification) for inclusion in the recommended specifications.‡

The modification referred to was the change of the spacing of the heavy driver axles from 5½ ft. to 5 ft., so that all wheel spacings are multiples of 5 ft., which makes a more convenient and simpler loading diagram. Although not as correct theoretically as the original 5½-ft. spacing, it is practically justified by various considerations; it departs somewhat (on the side of

* Cons. Engr., New York City.
† See p. 472.
‡ See p. 477.

safety) from the composite loading at the shorter spans, yielding a margin of stress-producing effect where it is most likely to be needed under future intensification of axle loads. The Cooper loading and the modified M-10 loading are shown on Figs. 18 and 19, respectively. The greater simplicity and convenience of the M-loading, as thus graphically presented, should require no further discussion.

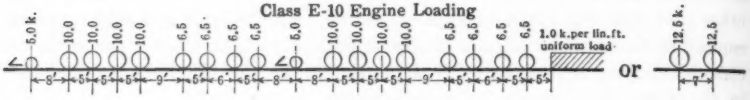

FIG. 18.

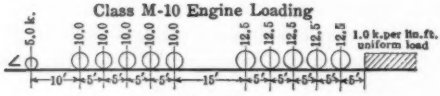

FIG. 19.

A wheel-load moment table for this M-loading is presented in Table 18,* of the Final Report on Specifications for Steel Railway Bridge Superstructure of the Special Committee on Specifications for Bridge Design and Construction. The corresponding table for the Cooper loading (Table 11† of the same report), does not compare with Table 18 in brevity and simplicity.

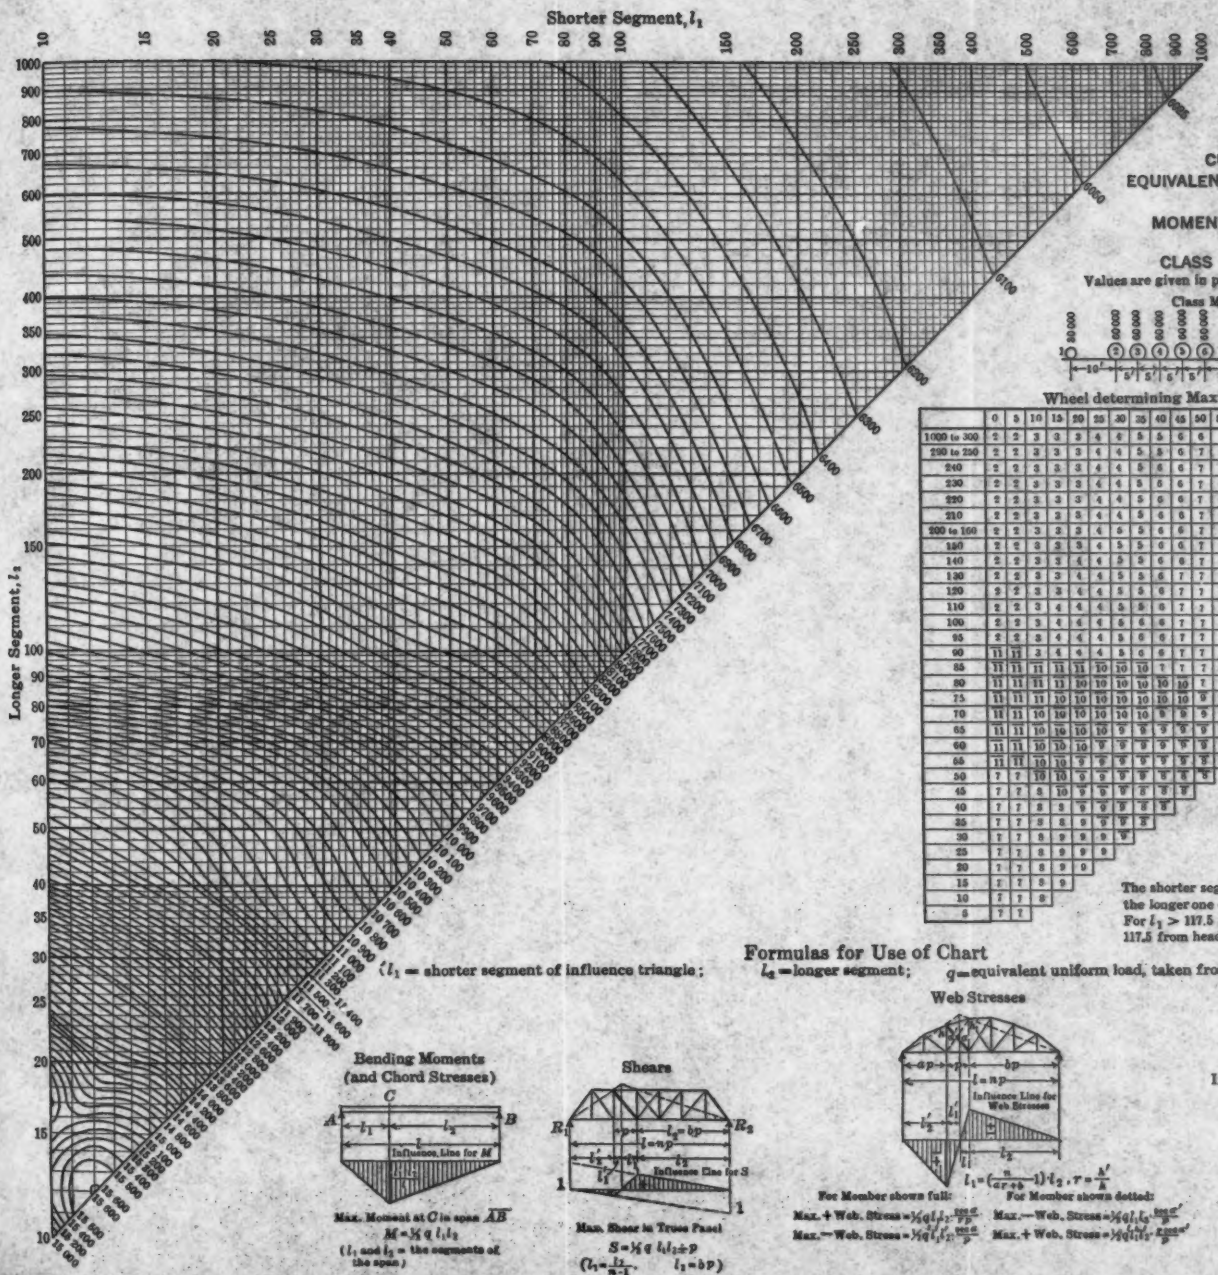
A diagram of equivalent uniform loads for the M-loading is presented in Fig. 20. A comparison of this diagram with Fig. 2 (which it supersedes) shows that the change from a 5½-ft. to a 5-ft. spacing has increased the stresses at the shorter spans about 5 per cent. A reference to Fig. 4, or Fig. 6, will show that this change is desirable, inasmuch as the previous M-loading was slightly deficient at those span lengths.

A chart of equivalent uniform loads for this M-loading is presented in Plate XIII (superseding Plate X). Plate XIII is extremely accurate and key diagrams have been added to facilitate its application. A table of wheel placements for maximum stress is also included. Plate XIII constitutes a complete and self-contained stress manual, and the writer recommends it as preferable to other tables or diagrams for obtaining stresses.

A graphic comparison of the approved M-loading with the Cooper loading and the composite loading is presented in Fig. 21. This diagram is similar to Fig. 6, which it supersedes. A comparison of Figs. 6 and 21 shows that the adopted modification of wheel spacing yields a desirable improvement of stress margin at short spans, at a slight sacrifice of scientific accuracy.

Fig. 22 presents a graphic comparison of the adopted M-loading with a modified loading formula which may be used as a "short-cut" for approximate results. This equation, for the M-10 loading, takes the simple form:

$$q = 700 + \frac{11\,000}{\sqrt{2\,l_1 + l_2}} \qquad (12)$$



* See p. 517.

Any Triangular Influence Line,

l_1 = Shorter Segment of Influence Triangle.
l_2 = Longer Segment of Influence Triangle.
q = Equivalent Uniform Load taken from Chart for the values of l_1 and l_2 Values given in pounds per linear foot per track.

This table can be used for figuring the maximum stress in any member or section of any span. It gives stresses equal to (or slightly greater than) the maximum stresses producible by the heaviest existing locomotive loadings.

For Maximum Bending Moment at any section of any span, l_1 and l_2 = the two segments of the span.
$M = \frac{1}{2} \cdot q \cdot l_1 \cdot l_2$

For Maximum End Reaction or End Shear, $l_1 = 0$ and l_2 = the span.
$V = \frac{1}{2} \cdot q \cdot l_2$

For Maximum Shear at any section of a span, $l_1 = 0$. l_2 = the longer segment of the span and l = the span.
$V = \frac{1}{2} \cdot q \cdot l_2 \cdot \frac{l_2}{l}$

For Maximum Floorbeam Reaction or stress in Hanger, l_1 and l_2 = the adjoining panel lengths
$R = \frac{1}{2} \cdot q \cdot (l_1 + l_2)$

FIG. 20.

in which,

q = the equivalent uniform load, in pounds per foot.
l_1 = the shorter loaded segment, in feet.
l_2 = the longer loaded segment, in feet.

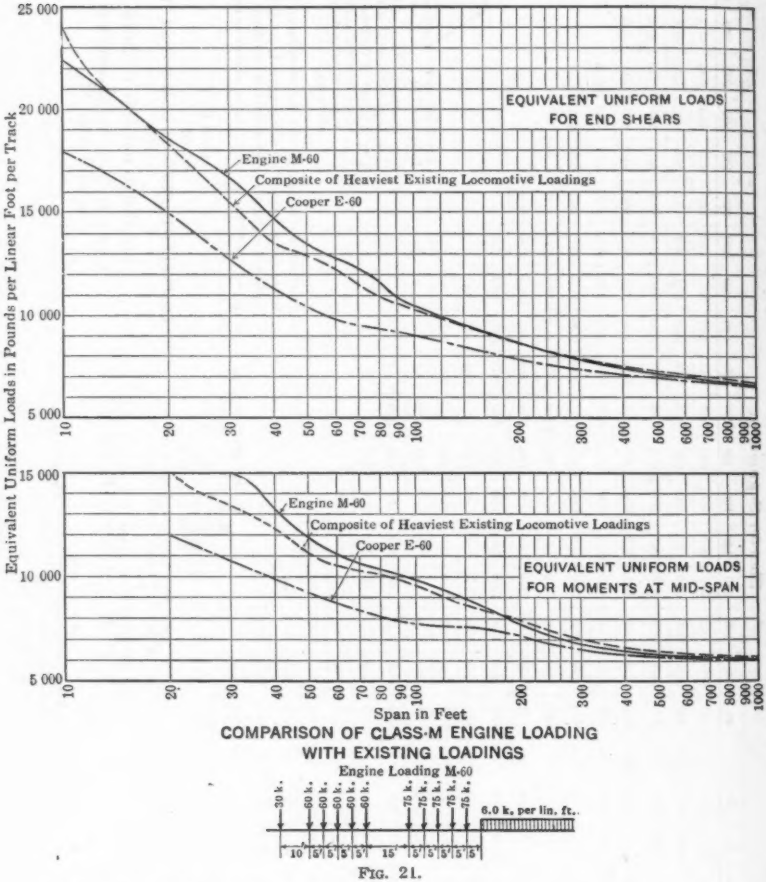

FIG. 21.

This loading formula reduces to:

$$q = 700 + \frac{11\,000}{\sqrt{\text{span}}}, \text{ for end shears} \quad (13)$$

$$q = 700 + \frac{11\,000}{\sqrt{l_2}}, \text{ for intermediate shears} \quad (14)$$

$$q = 700 + \frac{9\,000}{\sqrt{\text{span}}}, \text{ for mid-span moments} \quad (15)$$

The previous loading formula (Fig. 13) was developed independently of the typical engine diagram to approximate the composite loading; consequently, at some points, the respective variations of the two loadings (No. 1 and No. 3) from the composite loading were additive. In this discussion, the formula has been developed with the object of fitting the adopted M-engine diagram. Fig. 22 shows how closely this has been accomplished without sacrificing simplicity of coefficients. The coincidence could have been made closer by abandoning the use of round numbers in the formula. The introduction of the coefficient in the denominator permitted the independent adjustment of the moment and shear curves.

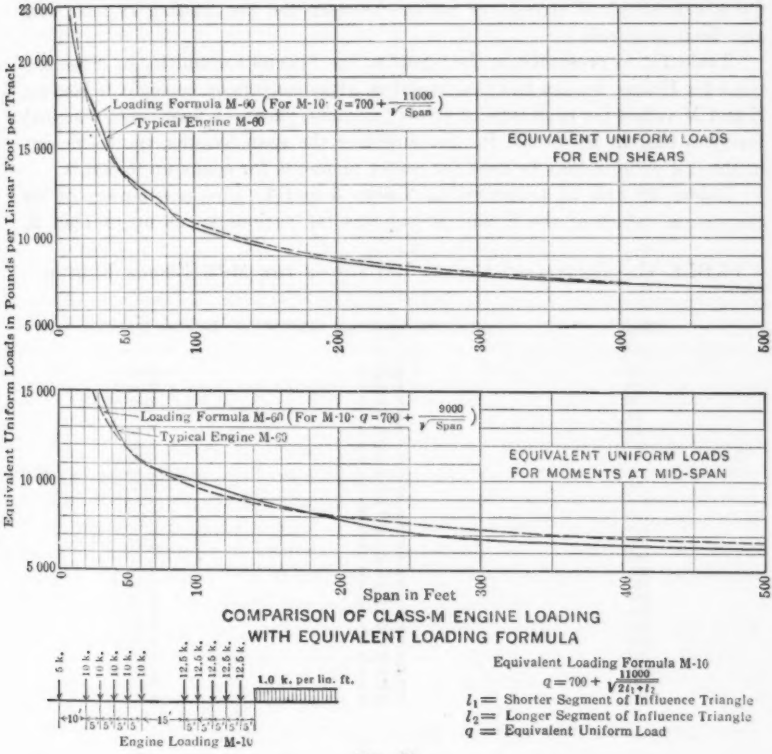

FIG. 22.

A table (Table 20*) of maximum moments, shears, and floor-beam reactions for the adopted M-loading has been presented by the Special Committee on Specifications for Bridge Design and Construction. Several of the discussors suggested the desirability of such a table to match the corresponding table which has been in use for the Cooper loading.

* See p. 519.

Other tables suggested in the discussions have been prepared for the adopted M-loading and also presented by the Committee. Table 21* gives the maximum bending moments at the various panel points of truss bridges for spans up to 450 ft., and Table 22† gives the shears in the various panels of truss bridges of spans up to 450 ft.

The argument that tables and diagrams are available for the application of the Cooper loading is nullified by the publication of the tables and diagrams for the M-loading just described. All tables and diagrams for the Cooper loading known to the writer are matched in form and scope by tables and diagrams for the M-loading. In addition, tables and diagrams which permit quick conversion of stresses or ratings between the two loading systems have also been prepared.

Table 17‡ as presented in the report of the Special Committee on Specifications for Bridge Design and Construction, gives conversion coefficients between E and M values for each type of stress (moment, shear, or floor-beam reaction) for span lengths up to 250 ft. By doubling the span lengths, the coefficients in the last column may be used for center moments for spans up to 500 ft.

Tables 11 and 12 (superseding Tables 3 and 4) give a summary of the conversion values of the E and M-loadings for various spans up to 1 000 ft.

TABLE 11.—EQUIVALENT COOPER RATINGS OF THE M-50 ENGINE LOADING.

Span.	E-rating for maximum moment.	E-rating for end shear.
10	E-62.5	E-62.5

900	E-50.3	E-51.6
1000	E-50.2	E-51.5

A conversion chart for changing E-ratings into equivalent M-ratings, for any point in any span up to 1 000 ft., is presented in Fig. 23. This diagram shows that E-60 is equivalent to M-45 at short spans and to M-60 at long spans.

The inverse chart for changing M-ratings into E-ratings is presented in Fig. 24. This diagram shows that M-60 is equivalent to E-81 at short spans, and to E-60 at long spans. For smaller indices, reduce the values in propor-

* See p. 520.
† See p. 526.
‡ See p. 516.

tion; thus, the equivalent of M-50 ranges from E-68 to E-50. With these tables and diagrams, the use of the M-loading is greatly facilitated.

Because of the great number of discussions received, it is practically impossible to answer them in detail, and it becomes necessary to confine this discussion to a review of the salient points that have been raised.

Although nearly all the discussions express a total or partial endorsement of the writer's conclusions, a number of dissenting views have been advanced.

TABLE 12.—EQUIVALENT M-RATINGS OF THE COOPER E-60 LOADING.

1 000	M-59.8	M-58.3

The discussions of this group make frequent reference, as authority for their position, to the decision of the American Railway Engineering Association in 1920 to retain the Cooper loading, based on studies presented in a Sub-Committee report by Messrs. Welty and Bouton.* Those studies were based on comparisons of modern locomotives and train loads with the Cooper standard, from which the authors arrived at the conclusion that the Cooper loading adequately covered the locomotives assumed.

The writer, assuming substantially the same locomotives and train loads, and following the reasoning outlined in his paper, arrives at the conclusion that the Cooper loading is unsatisfactory as a present-day specification and that a better loading can be devised.

In attacking this conclusion, the principal argument of the dissenting group is that the writer's study is based on extra heavy locomotives, not in common use. In reply, it may be pointed out that, with one exception, the locomotives considered by the writer are identical with the heavy locomotives considered in the report of the Sub-Committee of the American Railway Engineering Association, referred to previously. The assumptions are the same, but the conclusions are different. Those who endorse the report mentioned cannot consistently attack the writer's loading assumptions.

* *Proceedings*, Am. Ry. Eng. Assoc., January, 1920, pp. 511–520.

The writer would defend his loading assumptions, even if there had been no precedent to guide or justify him. He hoped he had made the logic of his argument clear. He based his studies on the heaviest existing locomotives, because they are the best index available of probable future development. History, in this respect, has repeated itself so often that it seems a lack of foresight to regard the present locomotive development as the limit of growth. Mr. Loweth, in his discussion, recalls the frequent arguments in the past that the limit of locomotive development had been reached, and writes: "Each

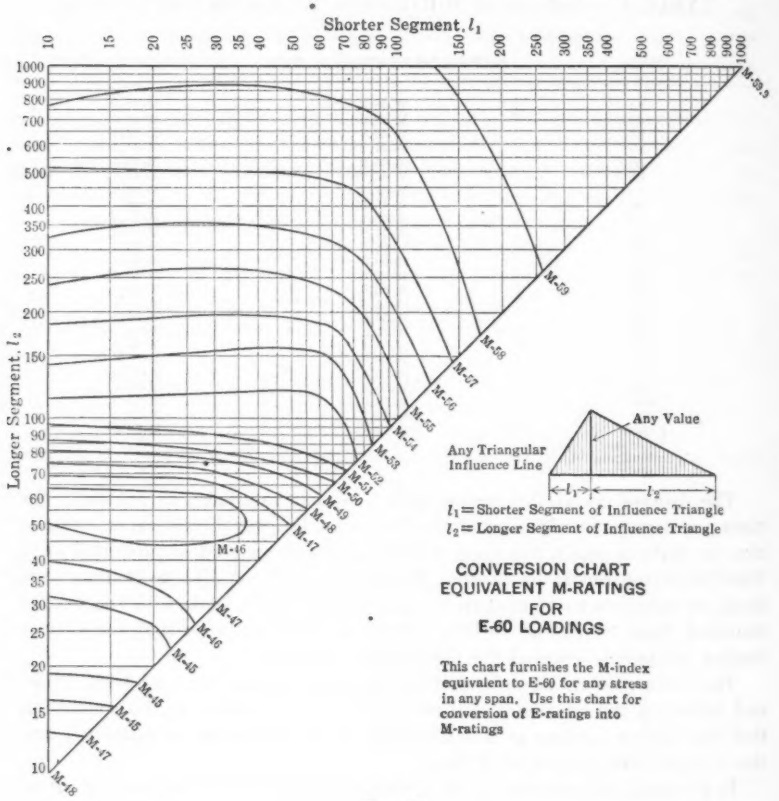

FIG. 23.

new locomotive seemed to be about the maximum that could be designed and would be practicable; yet, as the years passed, there was a continuing succession of heavier locomotives, and the end is not yet in sight." The extra heavy locomotives of yesterday have become the average locomotives of to-day; and the extra heavy locomotives of to-day will be the average locomotives of to-morrow. In the past, the life of bridges has been curtailed by loading augmentation; engineers should not be guilty of repeating that mistake. Bridges should

be proportioned to the loads of 25 or 30 years hence, not to the loads prevailing to-day. Loading diagrams should conform, as far as possible, to the expected future loads. Specifications should be progressive, not short-sighted. Good engineering in this field demands vision, based on recognition of the lessons of the past.

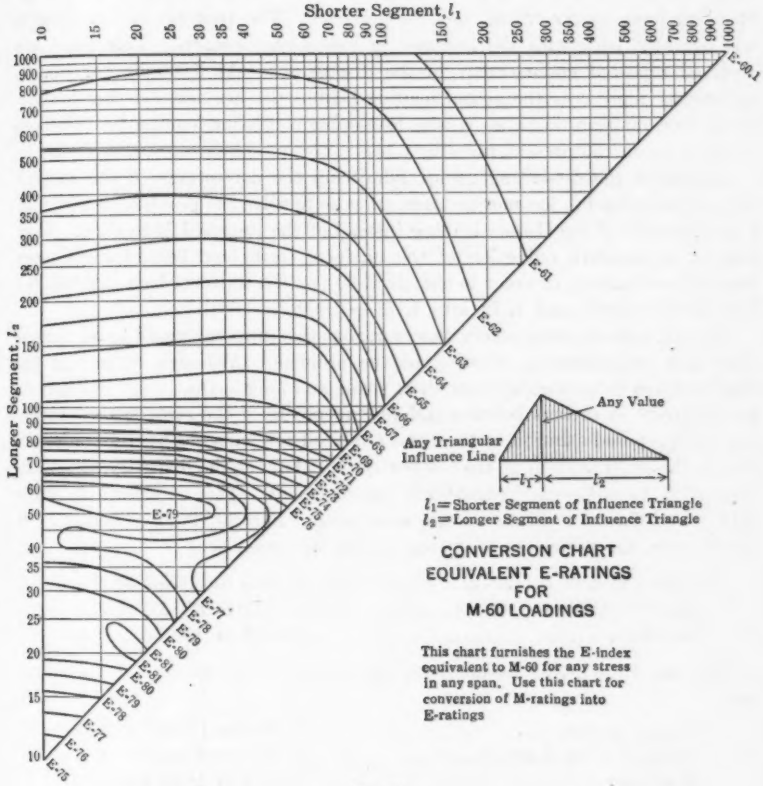

FIG. 24.

The next criticism by the dissenting group is on the assumption of train loading behind the locomotives entering into the composite loading. Influenced by their use of the Cooper loading, they contend that 6 000 lb. per lin. ft. is too light a uniform load to follow these locomotives. The answer is simple: The actual train loads following these locomotives scarcely equal and certainly do not exceed 6 000 lb. per lin. ft. In the report of the Sub-Committee of the American Railway Engineering Association, previously referred to, the train load assumed behind the same locomotives consisted of 210 000-lb. cars, amounting to only 4 770 lb. per lin. ft. The writer has been more generous in this regard than the authors of the report which is being cited as an

authority. On consulting the railroads in question, it will be found that the heaviest locomotives are used for hauling trains of cars weighing less than 6 000 lb. per lin. ft. Trains weighing 4 770 lb. per lin. ft. are assumed by the Pennsylvania Railroad Company behind its heaviest locomotives. The trains behind the heaviest locomotives of the Michigan Central Railroad weigh only 4 000 lb. per lin. ft. The locomotives are made heavy in order to haul longer trains, not heavier cars. The increase in car weights has not kept pace with the increase in locomotive weights. This point has received repeated endorsement in the discussions. As 6 000 lb. per lin. ft. generously represents the actual loading behind the heaviest existing locomotives, there appears to be no reason to assume a heavier loading behind those locomotives in the present investigation.

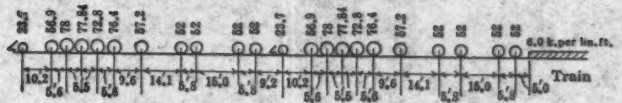
Others of the dissenting group, admitting the correctness of the writer's ratio of train load to locomotive loads, propose to solve the problem by adopting a modification of the Cooper loading instead of the proposed M-loading. They suggest a one-sixth reduction of the uniform train load behind the Cooper locomotive diagram, in order to change E-60 (with a uniform load of 6 000 lb.) into E-60 + 5 000, and E-72 into E-72 + 6 000.

Careful consideration shows, however, that this proposal would be an incomplete and unsatisfactory solution of the problem. Although correcting the disproportion in ratings between short spans and long spans, it will not correct the disparity in ratings between different members of the same span. Applying this proposed solution to the truss analyzed for purposes of illustration in Fig. 1, this modification of the Cooper system changes the disparity of ratings from 37% to 36%—an insignificant improvement. This is shown on Plate XIV for different loadings on the same span. For the Pennsylvania N-1-S locomotives, the variations in rating within this truss are:

Cooper system ..... E -54.7 to E -75.0 = 37%
Modified Cooper system..... E′-55.0 to E′-75.0 = 36%
M-system ..... M-46.2 to M-55.6 = 20%

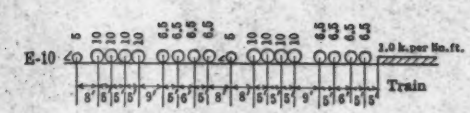
For the Erie 2-10-2 locomotives, the variations in rating for this truss are:

Cooper system ..... E -53.9 to E -68.4 = 27%
Modified Cooper system..... E′-54.2 to E′-68.4 = 26%
M-system ..... M-45.6 to M-50.6 = 11%



For the Pennsylvania I-1-S locomotives, the variations in rating within the 140-ft. span are:

Cooper system ..... E -53.5 to E -67.6 = 26%
Modified Cooper system..... E′-53.9 to E′-67.6 = 25%
M-system ..... M-45.4 to M-50.4 = 11%



Averaging the results for the three locomotives, the following values are obtained:

Cooper system ..... Average discrepancy = 30%
Modified Cooper system..... Average discrepancy = 29%
M-system ..... Average discrepancy = 14%

In other words, the proposed modification of the Cooper loading reduces the disparity of ratings within a given span by only 1%, whereas the adoption of the M-loading would reduce the error to less than one-half. These comparisons (Plate XIV) show that the suggested modification of the E-system does not solve the problem of disparity of ratings within a span. Neither will it correct the disparity of rating between two short spans, for example, between 40 ft. and 140 ft. In addition to this defect, the proposed modification of the Cooper loading would not avoid a revision of existing stress tables and ratings; and this revision would be more likely to cause error and confusion than a clean-cut change to a new system.

Once the disproportion of the standard Cooper system is recognized, the remedy is not to "patch up" that system with inadequate modifications, but to make a fresh start with a simpler one founded on modern heavy loadings and, therefore, better designed to cover future developments. If the M-system is admitted to be simpler and better than the E-system, engineers should not stop half way in correcting their standards, but should make a clean-cut change and thereby secure all the advantages of the new standard.

Another argument advanced against the proposed loading is that the majority of existing bridges are of spans of less than 100 or 120 ft., and that for these short spans the Cooper system yields a sufficiently close approximation to the stress ratios of modern loadings. This argument might have weight if the specifications were limited to spans of this length. It is true that if all spans were less than 80 or 100 ft., it would make comparatively little difference what system of loading specifications was used; but specifications are not limited to plate-girder spans. The A. R. E. A. Specifications include 300-ft. spans; the new specifications of the Special Committee on Specifications for Bridge Design and Construction, of the Society, are intended to apply to bridges of any span. If the Cooper system is satisfactory for plate-girder spans, but gives rise to serious discrepancies in longer spans, it should certainly be superseded by a loading system that gives consistent and harmonious results at all spans.

With the exception of the dissenting group, the arguments of which have just been reviewed, the general reaction to the writer's investigation and conclusions has been that of confirmation and endorsement. It is well expressed by the following quotation from the discussion by Mr. Strachan:

"* * * the author's determination of M-60 after careful study of the stress-producing effects of the heaviest existing locomotives, and his subsequent building up of a series of M-diagrams bearing simple ratios to M-60, in the manner of the Cooper loading, is an important step in the direction of introducing a scientific and modern standard load system for the economical design of railroad bridges and for the rating or comparison of their carrying capacities; a system of which the need is admittedly great in consequence of the changes in locomotive construction which have taken place since the Cooper system of loading was devised."

The individual discussions will now be reviewed in the order of their publication.

The criticism of Mr. Purdon, that the engines considered in the investigation are "enormous" or "exceptional" has already been answered. Even if all existing locomotives had been included in the analysis, the results would have been the same, as the object of the analysis was to determine the enveloping or maximum stress effects. No specification can be regarded as scientific or adequate unless it takes into account maximum stress-producing effects. Mr. Purdon's suggestion that bridges should provide for possible small engines "as a minimum" does not appear to be logical.

Mr. Purdon makes the point that the proposed typical engine (M-Loading No. 1) "does not resemble an engine". That, of course, is a matter of personal opinion. If the M-diagram does not resemble any particular engine, that is because it is a composite of different types, conventionalized and simplified. It combines the governing features of the Santa Fé or Decapod with those of the Mallet locomotive. As stated by Mr. Cochrane:

"Modern locomotives differ so greatly in the arrangement and spacing of axle loads that no single type can be found to represent all of them, unless it is a more or less conventional system, such as the author's first alternative loading. A composite loading derived from a number of different types of heavy locomotives will undoubtedly be more nearly representative of future loadings than any single loading series, and, consequently, will make more adequate provisions for future developments in locomotive design."

The point is also clearly covered by Professor Bird.

The proposed M-loading diagram may be regarded as an outline of a Mallet engine with different weights on the two sets of axles (for which there are precedents); or, it may be regarded as a Santa Fé or Decapod locomotive with the engine placed next to the train (for maximum stress). Resemblance to any particular type could easily be secured by minor modifications; but it would be at the expense of simplicity and symmetry.

Mr. Purdon attempts to demonstrate the adequacy of the E-loading by showing that a certain span designed for the Cooper loading gives satisfactory uniformity of stress under an E-42 double-headed Consolidation engine. This was naturally to be expected, as the Cooper loading diagram is a double-headed Consolidation engine. It is for types other than Consolidation engines, and for loads exceeding E-50, that the Cooper loading reveals its inadequacy.

Mr. Purdon gives figures showing the rapidly growing use of the Santa Fé type of locomotive, although its efficiency only slightly exceeds that of the Consolidation engine. He also shows the much greater efficiency of the Decapod or "ten-wheeler". In these conclusions, he is confirmed by Mr. Bland; but they serve only to strengthen the writer's position. Whether the Santa Fé or the Decapod locomotive represents the governing type in the future is immaterial in this discussion, as their stress-producing effects are practically identical; the proposed M-loading will provide for them, whereas the E-loading does not fit either. Plate XIV shows how the M-loading gives much better results for Santa Fé and Decapod locomotives than the Cooper loading. For the Decapod locomotive, the E-rating variation in a given span is 26%, whereas the M-rating variation is only 11 per cent.

Mr. Strachan points out the inconsistent accuracy of extreme precision in bridge designing when the fundamental loading assumptions are wrong. He characterizes the Cooper system as "an ancient generalization, which, although excellent in its day, has outlived its usefulness." He endorses the proposed M-loading, and states that "its adoption would tend toward augmented economy and the elimination of many unprofitable complications inseparable from the use of an obsolete load specification." Although preferring the typical engine diagram (M-Loading No. 1) as a load specification, Mr. Strachan suggests the use of the alternative loadings as "short-cuts" under suitable circumstances. This idea has been applied in Fig. 22 in which is presented a simple loading formula that may be used as an approximate substitute for the M-engine loading specification.

Mr. Cochrane supports the writer in his claim that the Cooper loading suffers from lack of balance between the locomotive axle concentrations and the uniform train load. He points out that, in the Cooper series, the maximum axle load is ten times as great as the train load per linear foot, whereas, in the case of the heaviest loadings now in use, this ratio is about 13. (This ratio for the Pennsylvania Railroad H-C-1-S locomotive, attains 14 or 15). Mr. Cochrane, therefore, agrees with the writer in the desirability of making the axle loads heavier than those of the Cooper series in proportion to the uniform train load.

For specification purposes, Mr. Cochrane expresses a preference for the loading formula (M-Loading No. 3) as being the simplest and most direct. He suggests, however, the use of an engine diagram (M-Loading No. 1) in conjunction with the formula as an approximate depicture of the loading. To reduce the discrepancy between the two alternative loadings, he proposes some modifications of the formula; but the writer submits Fig. 22 as a simpler solution of the problem.

Mr. Lucius predicts that the tendency in future bridge loadings will not be toward increased driver axle loads, but rather toward an increase in the number of drivers. This is an argument for the adoption of the M-system in preference to the E-system, as the increase in the number of drivers means the abandonment of the Consolidation type of locomotive for the more modern types on which the M-loading is based.

Mr. Lucius also raises the question of electrification and the new motor diagrams which it may develop. This is a question in regard to which it is difficult to come to any conclusion or to make any predictions at this time, as the standardization and development of electric motor diagrams is still in its infancy. Nevertheless, a study of the tendency in recent heavy electric locomotive diagrams indicates that the M-system will be better fitted than the E-system to the electric locomotives of the future.

Mr. Worthington emphasizes the fact that the present locomotive types have outgrown the Cooper loading diagram, and endorses the writer's conclusion that a material revision of this loading diagram is necessary in order to secure uniformity of stress and economy of metal. After a care-

ful study in conjunction with H. F. Passel, M. Am. Soc. C. E., he expresses a preference for the typical engine diagram (M-Loading No. 1).

Mr. Gilbert also confirms the writer in his claim that the Cooper loading does not suitably provide for modern types of engines. From his own investigations, Mr. Gilbert believes that a diagram of the Santa Fé type would properly represent modern locomotive loadings. He points out the increasing use of the Santa Fé type, and states, as his conclusion, that the Santa Fé is a permanent type which should be given full consideration in selecting a proper bridge loading. This conclusion appears to be incontrovertible. The writer would point out that the M-loading diagram contains the essential elements of the Santa Fé axle diagram, conventionalized and simplified; and he would call attention to the comparison previously mentioned, which shows how the M-loading is superior to the Cooper loading in representing the stress-producing effects of Santa Fé locomotives.

Mr. Gilbert characterizes the proposed M-60 loading as "equal to or greater than that of any locomotive now in service", and questions whether railroad executives will approve of such a heavy loading. The writer is convinced that the adoption of the present maximum (M-60) for the design of new bridges on main lines will be amply justified by the inevitable increase in loading during the life of those structures. However, if any railroad officials regard this loading as excessive, there is nothing to prevent them from using M-50 or M-55 instead; or, preferably, the unit stresses may be augmented so as to give the same weight of structure with M-60 loading.

In the proposed M-60 loading, each of the five heavy axle loads are 75 000 lb. Mr. Gilbert shows by tabulated data that average axle loads exceeding 60 000 lb. are common, and that axle loads of 78 000 lb. are in use. To this may be added the Pennsylvania H-C-1-S engine, which has axle loads of 86 400 lb. Mr. Gilbert admits that the tendency of driver axle loads is to increase (on account of the increasing demand for tractive power). In view of these facts, a loading specification (M-60) with 75 000 lb. on the driver axles, does not seem to be excessive if bridges are to be designed with any regard to future requirements.

Mr. Gilbert shows by diagrams (Fig. 15) the inadequacy of E-60 loading to provide for actual engines; he finds the resulting over-stress produced by Santa Fé locomotives in the shorter spans to be approximately 25 per cent. This would correspond to E-75 which is equivalent, at these spans, to M-60. Accordingly, Mr. Gilbert's diagrams demonstrate that M-60 is not too high a loading to protect new designs against present-day locomotives.

Mr. Gilbert emphasizes the importance of a loading specification which will give ample section to short spans, so as to provide the needed protection against corrosion to floor systems, hangers, etc. This requirement is fulfilled by the M-system as it corrects a relative deficiency of 25% in the Cooper loading for short spans.

Mr. Waddell generously endorses the writer's thesis. He discounts the argument for retaining the Cooper loading as a rating standard, declaring that the M-loading system provides just as convenient a rating standard.

Mr. Waddell expresses a preference for M-Loading No. 3 (the loading formula) as the most scientific and convenient; and he endorses the suggestion made by Mr. Cochrane that M-Loading No. 1 (the typical engine diagram) be used in conjunction with the formula as an approximate representation.

Mr. Lindenthal properly characterizes the subject as one in which meticulous accuracy is out of place. He expresses his preference for M-Loading No. 1 (the typical engine diagram), as it would represent the smallest departure from present methods, merely substituting a new and simpler wheel-load diagram for the Cooper diagram, and as it is sufficiently inclusive of the maximum effects of loads from any of the seven locomotive-wheel diagrams illustrated in the paper.

Mr. Lindenthal points out that the floor construction, consisting of short spans, suffers more than the trusses from an increase of locomotive weights. That is one of the writer's reasons for advocating a loading specification which will be relatively more generous to short spans than the Cooper specification. Mr. Lindenthal mentions the greater allowance for impact in floor members, but he confuses the issue by suggesting that this impact allowance covers to a certain extent unforeseen increases in wheel loads. The writer is of the opinion that the impact provision for short spans in present specifications is inadequate and cannot be considered as including a margin for load increase.

Mr. Lindenthal raises the question of relative impact (due to difference in speed) of freight and passenger locomotives. This point must await further experiment and, when determined, should be covered in the specification for impact. The writer does not believe, however, that light passenger locomotives at full speed will produce greater total stresses than the heavy axle loads at freight-train speed; in addition, the possibility of the heavy locomotives running over a bridge at full speed when relieved of train load, must be considered as well as the possibility of passenger trains being limited in speed in going over the structure. The subject of impact provision is a large problem in itself, and should not be permitted to obscure the issue in the present investigation. Moreover, even if Mr. Lindenthal is correct in his contention that passenger locomotives should govern in design, it does not affect the choice between the M-loading and the Cooper loading, as the trains behind passenger locomotives are much lighter than those behind freight locomotives, and the ratio of train weight to locomotive weight in passenger engines conforms to the M-loading and not to the E-loading. For example, the K-4-S passenger locomotive of the Pennsylvania Lines, with its following train load, is found to be closely and consistently represented by M-49.

Professor Caughey endorses the writer's thesis that the Cooper loading should be replaced by a loading more in agreement with the weights and axle groupings of modern railway rolling stock. He records his preference for M-Loading No. 1 (the typical engine diagram) and gives some cogent reasons for this choice.

Professor Caughey raises the question of train loads in exceptional cases being heavier than the engine, when light locomotives are used with short

trains of heavy cars. Any such exceptional case should receive special study in adopting a design load; if a suitable index is used, either the M-loading or the E-loading will give safe stresses for this case.

The writer is grateful to Mr. Ralston for his expressive review of the questions under consideration, and for his encouraging words of appreciation. Mr. Ralston endorses the writer's conclusions as to the erratics of the Cooper loading system, and advocates the adoption of the M-system as consistent and logical. He gives a striking review of the history of locomotive development, and records his conviction that the M-loading system will remain applicable for a long time to come.

Mr. Bland, in his discussion previously mentioned, contributes an interesting account of the introduction of the E-loading system. He recalls that the late Theodore Cooper, M. Am. Soc. C. E., gave the E-25 loading as a minimum, and the E-40 as a maximum, which latter he regarded as the heaviest loading possible. Among the disadvantages of the Cooper loading, Mr. Bland cites the incorrect axle-load ratios and distances, the fixing of a ratio between train load and axle load which was not applicable to loads above E-40 or E-50, and the inapplicability of the E-standard to engines other than those of the Consolidation type.

From considerations of locomotive development, Mr. Bland concludes that the E-loading is not applicable beyond Cooper's upper limit of E-40, and that, for many years, the Cooper loading has ceased to be a proper standard.

After condemning the inconsistencies resulting from the use of the Cooper loading (such as the necessity for different E-ratings for different parts of the same bridge), and recording his hope that the M-loading in one of its three forms will soon be adopted by the Profession, Mr. Bland expresses his own preference for M-Loading No. 3 (the loading formula) for bridge design. The writer is in sympathy with this preference for the loading formula, but regrets that conditions do not appear ripe for this innovation in loading specifications. If M-Loading No. 1 (the typical engine diagram) is adopted as a general specification, the individual designer may use a loading formula (either that of Fig. 13 or Fig. 22) as a sufficiently close equivalent.

Mr. Bland endorses the writer's underlying principle of a composite loading, and recommends that each railroad "consider the group of its engines for which it wishes to provide, form a 'composite' of such engines, and then choose the M-loading (taking into account future development) that best fits its case, and use such loading in its specifications." According to his correspondence with the writer, Mr. Bland has done this for the engines of the Pennsylvania System, and has established a series of M-loadings which give consistent protection to the various types of locomotives in use.

Based on considerations of comparative efficiency, Mr. Bland makes a prognosis of future engine development. He shows that the development of the Mikado type (2-8-2) is a step in the wrong direction, but that the Decapod type (2-10-0) offers the greatest advantages. The I-1-S engine (Decapod) yields 69% more tractive power than the H-10-S (Consolidation), with an increase of only 45% in the weight of the engine. Accordingly, he concludes that the Decapod type is more likely to be increased in the future than other

types. As the stress effects of the Decapod and Sante Fé types are practically the same, either may be considered as a governing type to which a correct loading specification should conform in order to provide for the most probable future development.

Mr. Johnson admits the defects of the Cooper loading as applied to roads using the heavy locomotives of the present day. He points out, however, the great mileage of roads on which lighter locomotives prevail, and he considers the Cooper loading satisfactory for such lines. In reply, the writer would state that the M-loading (with the index reduced from M-60) would be just as satisfactory as the E-loading for these lines, and a loading standard (like the M-series) which can be used on all lines, both heavy and light, is obviously preferable to one which is limited in application to second-class roads.

Furthermore, Mr. Johnson admits that Santa Fé locomotives are a governing type on these lighter roads, and the writer has previously shown that the M-loading gives more consistent protection than the E-loading to engines of the Santa Fé type. It may also be noted that the secondary lines referred to generally have steeper grades and sharper curves, requiring heavier locomotives in proportion to the weight of the train; and the M-system, with its correction of ratio of engine weight to train weight, will fit this loading better than the E-system.

Mr. Johnson admits that the proposed M-loading is in the right direction, but thinks its application to the lighter lines of the country should be deferred. As opposing this view may be urged the desirability of a uniform standard for all lines. If the advantages of the M-system for the main lines are admitted, considerations of uniformity would argue for the adoption of that loading system for all lines. M-50 or M-60 can be used on the main lines and M-40 or M-50 on the lighter lines, depending on the governing types and weights of locomotives.

Mr. Rogers admits that the M-60 loading covers all stresses in all spans from the five heaviest present-day types of engines. He adds that the proposed conventional loading would conform admirably to the requirements if all these five types of locomotives were in use on any one railroad; otherwise, he argues, there will be a waste of material put into bridge structures to suit the requirements of engines of foreign roads. In this argument, Mr. Rogers misses the underlying principle of the writer's paper, namely, that a composite loading is the most scientific solution of the problem of devising a single standard to fit all engine types with a view to future development. Such comparisons as those illustrated previously show that the M-loading (based on the composite) yields sufficiently close agreement with individual engines entering into the composite; certainly a much closer agreement than that provided by the Cooper loading. Inasmuch as disproportion of stress means waste of material, the comparisons given demonstrate that designs made with the M-loading will involve less waste than if the E-loading is used.

Mr. Rogers also raises the point that lighter engines are not reduced models of the heavy locomotives which entered into the composite. The fact is,

however, that although the M-loading may not be a correct pictorial representation of these lighter locomotives, it will be found to yield correctly proportioned designs. Mr. Bland, who has made special studies along this line, has found the M-loadings to give uniform and consistent results for the lighter engines on the Pennsylvania Lines; for instance, he found that the Mikado and Consolidation locomotives are correctly and consistently represented by M-50 as a design load. (According to Mr. Bland's graphs and conclusions, the L-1-S Mikado is economically protected by M-50; the K-4-S passenger locomotive by M-49; the H-10-S Consolidation by M-47; the H-8a-S by M-45; and the H-6b-S by M-42.)

Mr. Rogers adds the argument that if the locomotives on any line reasonably conform to the Cooper loading, the use of the M-loading would involve a waste of metal at short spans. The answer to this is the fact that the disproportion between long and short spans arises mainly from the incorrect ratio of train load to locomotive loads in the Cooper system. A change in type of locomotive does not alter this condition. With proper reduction of the index, the M-loading will give consistent results for the conditions assumed by Mr. Rogers. However, if there is any excess of metal in short spans resulting from the use of the M-loading, that extra metal is in a good place. A loading that adds extra metal to floor systems and short spans is unquestionably preferable to one which skimps the short spans and wastes metal on the long spans.

Mr. Rogers recommends that instead of adopting the M-loading with varying index, each railroad should devise its own special loading for design. The writer submits that this would result in confusion of ratings and comparisons, and would be far from a solution of the problem.

Mr. Stone recommends the new loading system as a step in the direction of filling a recognized need. He expresses a preference for M-loading No. 1 (the typical engine diagram), because, with suitable tables, it would be as simple to apply as any other method. He suggests the appointment of a committee to consider the question of endorsing the proposed M-loading. This has already been done by the Special Committee on Specifications for Bridge Design and Construction.*

Professor Bird, in his discussion previously mentioned, endorses the writer's conclusions and reports that he has calculated a number of designs using the M-loading, and has been pleased to note how well the values fitted the maximum moments and shears producible by actual locomotives.

He refers to the charts of equivalent uniform loads devised by the writer (Plates IV, VI, XI, and XIII) and suggests that it would be well to explain and illustrate the use of these charts with typical problems. Instead of taking space in this discussion, the writer would refer the readers to the explanation and illustration of these charts published elsewhere.†

Professor Bird also suggests that tables of moments and shears for the M-loading would be a helpful addition to the paper. Such tables were also

* See pp. 472, 477.

† *Engineering News*, April 22, 1915; "American Civil Engineer's Handbook," 1920, pp. 849, 853, 854, 884, 904, 906 and 908; and *Lefax*, September, 1920, No. 10–348.

prepared by the writer at the request of the Special Committee on Specifications for Bridge Design and Construction and are incorporated in the report of that Committee.*

Professor Bird endorses the idea suggested by Mr. Seaman, to include both the E-loading and the M-loading in the specifications, in order to make the change optional during the transition period.

Professor Fuller, in his discussion, endorses the writer's conclusions. "The Cooper loading", he states, "no longer represents even to an approximate degree the modern locomotives and trains."

Professor Fuller declares his preference for M-Loading No. 1 (the typical engine diagram), and raises the interesting question of the flexibility of the loading formula (M-Loading No. 3), suggesting that re-adjustment may be found necessary after the M-loading has been in use half a century or more. In reply, the writer would point out that the loading formula (Equation (4)) contains two numerical coefficients; by modifying one or both of these coefficients, the curves of equivalent uniform loads in Fig. 13 may be raised or changed in slope to conform to any requirements. In the modified form of the loading formula (Equation (12)), there are three numerical coefficients, giving still greater flexibility. By modifying the coefficient of l_1 in the denominator, the curve for center moments may be adjusted independently of the curve for shears. Fig. 22 is a graphic demonstration of the flexibility of this loading formula, as curves have been obtained to coincide so closely with the arbitrary curves of a typical engine diagram. The coincidence could have been made still closer by deviating from the round numbers chosen for the three coefficients in the formula.

Professor Bishop emphasizes the conclusion that the Cooper loading has outlived its usefulness and should be replaced. After calling attention to the disproportion and lack of simplicity of the Cooper loading, Professor Bishop expresses a fundamental principle when he states: "Any new loading should give approximately the same results as the actual loads which are likely to be used in the near or distant future." In this connection, he strongly recommends the writer's loading formula (M-Loading No. 3), as overcoming the objections heretofore advanced against equivalent uniform loads, and as yielding stresses which "provide for any of the critical engines of to-day, and, probably, by proportion, for those of years to come."

Mr. MacCornack also endorses the writer's paper, and recommends the proposed wheel-load diagram (M-Loading No. 1) as fairly representative of the actual loads in use. He would adopt such a system of wheel concentrations for examining existing structures and for designing bridge floors and short spans, and would use a loading formula equivalent to M-Loading No. 3 for designing all other bridge members. If preferred, he suggests, the load formula (M-Loading No. 3) might be modified to coincide more closely with the engine loading, and such a modification is submitted by the writer in Fig. 22. Mr. MacCornack rightly emphasizes the point that the important consideration is not the form of the loading specification, whether it is an engine diagram or an equivalent uniform load formula, or any modification

* See pp. 495-531.

of them, but that the loading adopted should represent correctly conditions in all parts of the bridge structure.

Mr. Disney endorses the writer's thesis. He regards all three of the alternative proposals as having distinctive advantages over the present methods, but considers M-Loading No. 3 as ideal, as "it is a formula which can be memorized and used, without tables or charts, to find the moments and shears at any point of a span by a simple slide-rule operation."

Mr. Disney, however, questions the applicability of the M-loading to Canadian railways on which, he states, the Santa Fé type is the present limit of locomotive development. In reply, the writer would direct attention to Plate XIV, which shows that the M-loading is better adapted than the Cooper loading to give economical protection to Santa Fé locomotives.

Mr. Ammann admits that unquestionably the proposed M-loadings have the advantage over the Cooper loading of greater simplicity. He points out, however, that the Cooper loading has been widely adopted as a standard, and that tables and diagrams are available to simplify the calculation of stresses for that loading. In reply, the writer submits that the mere fact of any standard being already in use is insufficient justification for retaining it when it is found to yield disproportionate and uneconomical results, and that the argument of tables and diagrams being available for applying the Cooper loading is cancelled by the publication of a complete set of similar tables and charts for the M-loading.

Mr. Ammann makes the statement that the proposed M-engine bears no greater similarity than the Cooper engine to any of the seven heaviest existing engines and those likely to be evolved in the future. The writer submits that this statement is refuted by a glance at the diagrams of the engines under consideration. The 5-axle grouping, which is the essential feature of the Santa Fé and Decapod engines, and the double set of drivers, which is the essential feature of the Mallet engines, are both included in the M-engine diagram, and neither of these features is represented in the Cooper engine diagram. What is more important, the M-loading is a more correct representation than the Cooper loading of the stress-producing effects of Santa Fé and Decapod engines, which represent the leading and most significant types of modern and prospective future engine development.

Mr. Ammann claims that the Cooper loading agrees as closely as the M-loading with the composite of the heaviest existing loadings; but, in his attempt to prove this, he does not take the Cooper loading as ordinarily specified and understood, but devises instead an arbitrary modification of the form E-72 + 6 000. This does not meet the issue, as this is not the Cooper standard under consideration, but a new loading devised to overcome one of the deficiencies of the Cooper standard. Fig. 6 shows the correct comparison, which clearly refutes Mr. Ammann's contention.

Mr. Ammann also claims that there are large discrepancies between the M-60 loading and individual heaviest existing engines. If such discrepancies exist, they are merely the inevitable variations between a maximum composite and its lesser components, variations which are on the safe side and which

provide a desired margin for future increase of stress at temporary low spots in stress-producing effects or in locomotive development; they are variations which will be reduced by future development toward the maximum composite instead of being (as in the case of the Cooper loading) variations which will become worse with the progressive departure of locomotive design from an outgrown standard.

Moreover, as shown by Plate XIV, for individual engines of the dominant types, the discrepancies of the M-loading are much smaller than those of the Cooper loading.

The suggestion of correcting the disproportion in the Cooper loading by changing the ratio of train weight to locomotive weight, made by Mr. Ammann, has already been answered. The proposed modification will upset existing ratings and lead to errors, and will only partly solve the problems under consideration. It will not correct the disproportion of stress within a given span, nor the disparity of ratings between different short spans, and it will not obviate the need of revising existing stress tables and ratings. If any change is to be made, no half-way measure should be used in correcting the standards; a fresh start, based on the latest developments, will prove more satisfactory in the long run than attempts to tinker with an outgrown standard.

Mr. Ammann suggests the possibility that the weights of locomotives and cars may continue to increase at different rates. As it is impossible to foretell future relative development, the writer submits that the present-day ratio of driver weights to car weights constitutes the best basis available for establishing a new loading specification. It is unquestionably a more logical basis than the outgrown ratio which obtained a generation or more ago. Mr. Ammann's suggestion of a flexible specification in which the individual engineer may arbitrarily vary the ratio of the uniform train load to the engine concentrations would only lead to chaos in standards, ratings, and stress tables.

Mr. Seaman endorses the writer's paper and conclusions and predicts that in the future bridges will be designed for the M-loading. He mentions the conversion tables which will facilitate the altering of recorded ratings of the railroads; with this object in view, the writer has added the conversion tables (Tables 11 and 12), and the conversion charts (Figs. 23 and 24) to this discussion, and has prepared the conversion table (Table 17) published in the report of the Special Committee on Specifications for Bridge Design and Construction.*

Mr. Mead also endorses the writer's paper. He declares that the necessity for revision is apparent, and points out that the present loading system gives unbalanced designs.

Mr. Mead strongly endorses the writer's conclusion that train loads and locomotive loads have not increased in the same ratio. The contention that the writer assumed an insufficient train load behind the modern locomotives considered in this paper, is answered by the following quotation from Mr. Mead's discussion:

* See p. 516.

"At present, train loads do not exceed 6 000 lb. per lin. ft. of single track, except in a few instances which will not affect the conclusions reached. Furthermore, the present design of cars must be changed so radically, in order to increase this train loading, that it seems as if this uniform load would represent a maximum train loading for an indefinite period."

Mr. Mead expresses a preference for M-Loading No. 2 (the uniform load plus spot loads) for its simplicity, flexibility, and ease of application.

Mr. Keith endorses the writer's paper and adds an interesting review of some early loading specifications. A useful lesson may be derived from Mr. Keith's account of a specification adopted by the New England Railroad Company in 1882, consisting of a live load headed by a Consolidation locomotive—a new type at that time—with four driving axles of 24 000 lb. per axle. This specification was criticized and ridiculed, many railroad men declaring that such a heavy engine would never be built. "Within three years that road had engines in use heavier than those that had been considered as excessive." History repeats itself; and engineers continue to make the mistake of under-rating future development.

Mr. Lang disagrees with the writer's conclusions with an animus which, under the circumstances, it is difficult to understand. The writer has simply given his best efforts to the analysis and study of a problem which appears to be of importance and of general interest, and it would be regrettable if such investigations are to be taken out of the field of sincere professional discussion into the domain of factional controversy.

If, as Mr. Lang states, the paper gives the impression of being "primarily an attack on the Cooper system of loading", that was far from being the writer's intention. The writer joins with Mr. Lang and others in a sincere admiration of Mr. Cooper's contribution and in a full appreciation of its past value in bridge design; but, as has been pointed out by others as well as the writer, the Cooper loading diagram has outlived its usefulness. It has served its purpose well, but new conditions have arisen as a result of locomotive developments far exceeding Mr. Cooper's anticipations, and surely engineers may make revisions to suit these new conditions without detracting credit from the pioneer who blazed the trail. The writer's position in this matter is that expressed by the dean of railroad bridge engineers, Mr. Bland, who has stated that, "if Mr. Cooper was still alive, he would share this view and be among the first to devise a new method and one which not only conformed to existing engines and train loads, but looked forward and beyond."

The principal criticisms made by Mr. Lang have been answered at length. The selections of engines and following train loads in the writer's investigation have been fully explained and defended; they have received the confirmation and endorsement of many eminent bridge engineers as the correct and proper basis for a modern loading specification.

Mr. Lang's question why the special engines used by the writer should be followed by a train load of only 6 000 lb. per lin. ft., is answered by the simple fact that that is the maximum weight of train load actually used behind the engines under discussion. In fact, the heaviest cars to be found behind these

locomotives are generally 210 000-lb. coal cars, which give a maximum train weight (with all cars carrying full overload) of only 4 770 lb. per lin. ft.

If these modern engines and their actual following train loads are compared with the E-40 loading, confirmation will be found of the statement challenged by Mr. Lang, that "the axle concentrations have increased 100%, whereas the weight of train per linear foot has increased barely 50 per cent." This disproportion is still further accentuated when the Pennsylvania H-C-1-S engine with axle loads of 86 400 lb. is considered.

Mr. Lang contends that the Cooper E-73 with a train load of 7 300 lb. per lin. ft. "more nearly approximates present-day equipment and rolling stock." With the exception of some special ore cars, trains will not be found exceeding 6 000 lb. per lin. ft. As a rule, the maximum train weight is considerably less than this figure, even behind the engines which Mr. Lang characterizes as "extreme".

Mr. Lang criticizes the M-loading as perpetuating a material difference in the effect of the engine and train load on bridge structures. The same criticism also applies to the E-loading; the essential distinction is that the Cooper loading would perpetuate the ratio that obtained more than thirty years ago, whereas the M-loading makes a fresh start with the ratio that obtains to-day. If there was any practical way, without compensating disadvantage, to make the specification flexible in this respect, the writer would welcome it; in the absence of such expedient, it is surely preferable to base a specification on the present ratio than to perpetuate a ratio that has long been outgrown.

Mr. Lang questions the writer's suggestion that design loads should be 25 to 50% heavier than the average present loading. The writer merely made this suggestion in the light of repeated past experience with the obsolescence of bridge structures under unanticipated load increase. This subject is involved with the question of proper unit stresses. Where a unit stress of 20 000 or 24 000 lb. per sq. in. would be justified, the current practice is to use only 16 000 lb. per sq. in., in order to provide for a possible load increase of 25 or 50 per cent. The writer maintains that it would be more rational and would give better designs to increase the assumed live loads instead of reducing the unit stresses. Designing with ultimate unit stresses for ultimate anticipated loads will give the best proportioned structures, with the metal distributed where it will do the most good in insuring their longevity. When this fundamental principle receives recognition in specifications in the form of increased unit stresses, the design load can properly be augmented from M-50 to M-60 or M-75.

Mr. Lang submits a table of E-ratings for M-60 (Table 10), in which he shows apparent errors in the writer's figures by comparison with his own. The values which Mr. Lang gives are taken from Table 2, which refers to the composite loading; whereas, he should have calculated his values from Table 3, which refers to the proposed typical engine loading (M-Loading No. 1). In addition, Mr. Lang has included in his figures the alternative loading of two axle concentrations which are not a part of the Cooper loading, but have

been added to it (with variations) to correct some of the deficiencies of that loading at short spans. (In the proposed M-loading, the necessity for such alternative concentrations is obviated.) With these corrections, the apparent errors in the writer's values will be found to vanish.

Mr. Lang attempts to show that the proposed M-loading does not vary appreciably from the Cooper system of loading, but his own values in Table 10 are a sufficient refutation, as they show a variation of 27% in the E-rating for M-60, from a maximum of E-77.3 at a 40-ft. span to a minimum of E-61.0 at a 300-ft. span. A variation of 27% is not one to be ignored. With the modified M-engine diagram adopted by the Special Committee on Specifications for Bridge Design and Construction, the variation from the Cooper loading is still greater, amounting to 38 per cent. (See Table 17*.)

Mr. Lang also attempts to prove that the Cooper loading fits the composite of the heaviest locomotives better than the proposed M-loading. Inspection of Fig. 4 and Fig. 6 will prove the contrary. Fig. 4 shows that with the exception of a few isolated points, the M-loading agrees with the composite within 1%, for all points of all spans up to 1 000 ft.; the few larger variations found are confined to very short spans, with extreme values of — 4 and + 6 per cent. Fig. 6, as well as Plate IX, shows that the Cooper loading varies from the composite by about 25 per cent. If E-60 is used, this variation from the composite is found at short spans; if E-73 or E-75 is used, the 25% variation is found at long spans. Mr. Lang uses E-73, but omits the long spans from his diagram (Fig. 17), so that the 25% variation from the composite is not revealed.

With the modification of the M-loading shown in Fig. 19, the variation of M-60 from the composite has been augmented at short spans, on the side of safety; but even with this increase, M-60 shows less variation from the composite than E-73. The maximum variation of center moments from the composite is 21.3% for E-73 and only 11.9% for M-60, and the maximum variation of end shears from the composite is 18.3% for E-73 and only 9.3% for M-60. Even this comparison is not fair to the M-loading, as these variations of M-60 from the composite are confined to the shortest spans and represent an excess intentionally introduced for the better protection of these short spans in which stress effects are most likely to be increased by future developments.

Mr. Lang emphasizes the point that it would involve too much work to re-classify the 250 000 railroad bridges in the United States. This would not be necessary. Moreover, it will be found that very few railroads have made much headway in "Cooperizing" their lines; the bridges for which E-ratings have been calculated and recorded constitute a small proportion of the total. For the bridges as yet unclassified, it will be as easy to fix the M-ratings as the E-ratings; and for the others, even if deemed necessary, it requires very little work per structure to translate E-rating to M-rating by means of a conversion table or chart (Table 17,* as presented by the Special Committee on Specifications for Bridge Design and Construction, mentioned previously,

* See p. 516.

Tables 11 and 12, and Figs. 22 and 23). This conversion to M-rating will soon be justified in the time saved in judging the capacity of the structure for heavy loadings.

Mr. Lang makes a special point of showing that about 96% of the railroad bridges are less than 120-ft. span, and that at less than that span the differences between the E-loading and the M-loading are unimportant. The spans exceeding 120 ft. may be only 4% of the total number, but they are considerably more important than that small percentage would indicate. A single long span may outweigh, in importance and in cost, a hundred small viaduct spans in its approaches. One would not think of limiting the specifications to 120 ft., and letting all longer spans take care of themselves. Engineers are not writing specifications limited to plate-girder spans. Moreover, a glance at Plate XIV, or Table 17* of the report of the Special Committee on Specifications for Bridge Design and Construction, reveals a considerable difference between the M-loading and the E-loading even in short spans; Table 17* shows that M-60 is equivalent to E-83 at a 35-ft. span and to E-69.8 at a 98-ft. span, or a variation of 19% below a 100-ft. span.

Mr. Welty is one of the authors of the Sub-Committee report† which influenced the American Railway Engineering Association to retain the Cooper loading in 1920; and, in his discussion of the writer's paper, he maintains his preference for the Cooper loading "with possibly a modification in the uniform load following the series of wheel loads."

Mr. Welty's argument that most railroad bridges have span lengths of less than 100 ft. and that, for such spans, it makes little difference what loading is used, has already been answered.

For longer spans, Mr. Welty points out that the difference between the loadings can be corrected by changing the Cooper loading, using E-73 + 6 000 instead of the Cooper standard, E-73 + 7 300. This suggestion has already been discussed at length, and it has been shown that this would not be a satisfactory solution of the problem. Plate XIV shows one of the reasons. It would not be as good a solution as a change to M-60.

Professor Williams endorses the writer's investigation as promoting economy, adequacy, and consistency in bridge design. He declares that, in a sense, the Cooper loadings have been a deteriment to structural engineering, and that lack of balance in most designs resulting from the application of the E-rating to express modern loadings even exceeds the 37% given by the writer.

Of the three forms of loading specification proposed, Professor Williams expresses a preference for the typical engine diagram (M-Loading No. 1), as he considers equivalent uniform loads insufficiently accurate to represent the actual effects of wheel concentrations. This point, however, is open to considerable difference of opinion.

Professor Williams emphasizes a point which the writer has made elsewhere, namely, that the problems of loads and stresses are interrelated. The present working stress of 16 000 lb. per sq. in. is too low. To provide properly for

* See p. 516.

† *Bulletin*, Am. Ry. Eng. Assoc., January, 1920, p. 511.

future increase, the factor of safety should be inserted in the loadings rather than in the unit stresses. The correctness of the principle of "ultimate loads with ultimate unit stresses" cannot be denied, and the Profession will have to come to its acceptance. This thought has been the basis of all the writer's studies for his paper, and may help to explain why his recommendations of design loadings are higher than those customarily regarded as adequate.

Mr. Jones weighs the difficulties involved in arriving at a uniform loading specification of enduring application. He endorses the indictment of the Cooper system because of the discrepancies between it and present-day developments, and indicates the reasons for the use by so many railroad companies of loadings other than the Cooper loadings. Although a new specification derived on essentially the same assumptions as those of Cooper may prove to be subject to the same local limitations in the light of future developments, Mr. Jones agrees in the desirability of making a fresh start and of having a uniform loading specification throughout the United States. He expresses the hope that, "even though the permanency of a new standard adopted to-day may be voted dubious, one may be adopted, if only as a second step toward the ultimate."

Mr. Jones prefers the typical engine diagram (M-Loading No. 1) as an outline which can be easily reviewed as mechanical developments are made. He, therefore, chooses it for publication in the specifications; he points out, however, that the designer will probably forget the wheel-load diagram, paste the table (Fig. 20), or chart of equivalent uniform loads (Plate XIII), in his handbook, and, perhaps, memorize the equivalent loading formula (Equation (4) or Equation (12) for emergencies, and thereby save precious hours of computation.

Mr. Woodruff endorses the writer's argument that the Cooper loading does not fit present conditions, and emphasizes the fact that the divergence is likely to be increased by future developments.

Commenting on the proposed M-loading, Mr. Woodruff raises some questions which have already been discussed. His objection on the ground that some of the locomotives considered by the writer are in limited use, is answered by the argument that these locomotives represent the maximum of each of the modern types and were considered merely as the best indication of the trend of future development. He suggests that the M-loading does not provide adequately for short spans (although it does so more generously than the Cooper loading). The writer has anticipated this suggestion by changing the spacing of the heavy drivers in the M-engine diagram from 5½ ft. to 5 ft.

Mr. Woodruff suggests an increase of 10% in the uniform load of the proposed M-loading on the ground that in the future the train load may increase more rapidly than the engine load; but the writer, guided by past experience and supported by others in these discussions, does not agree with this prediction. The economics of railroad operation demand continued development and augmentation of locomotive weights, but not of car weights. The question of relative train load affects only the long spans; and for those spans the lower average weight (per linear foot) of long trains should be taken into account.

Mr. Woodruff declares his preference for M-Loading No. 1, as it facilitates judgment of heavy shipments.

He suggests designing directly for M-75, both for simplicity and economy; but this is exactly what the writer meant when he recommended designing for the M-60 loading with a provision for 25% overload; he expressed it in that form in order to keep before the designing engineer the intent of the 25% margin, and the thought that the unit stress may then be justifiably increased from 16 000 to 20 000 lb. per sq. in.

Mr. Thomson endorses the writer's paper. He points out that there is more uniformity now than in the past in the loadings used by different railways, and emphasizes the importance and value of proper standardization in this field.

Professor Young characterizes the data presented by the writer as "so convincing as to leave no other course open than to revise the present obsolete locomotive loadings." He adds: "The author has established that, for heavy loadings on first-class railway systems, the Cooper system is inadequate and that the new proposed system would give safe and logical results." Professor Young expresses the hope that the American Railway Engineering Association will reconsider its decision to abide by the Cooper system.

Although Professor Young endorses the M-loadings as "admirably suited to the heavier lines operating with steam locomotives," he questions whether they are as closely applicable to average or second-class lines. Plate XIV shows that any line on which Santa Fé engines are operated will be better protected by the M-loading than by the E-loading. Mr. Bland, of the Pennsylvania System, has found, from independent studies, that the M-loading is also admirably adapted to protect Consolidation and Mikado locomotives. The M-equivalents found by him are given on page 710. Accordingly, for average or second-class lines, even those on which a Mallet locomotive will never be used, it will be found to be safe and economical to adopt the M-loadings.

Professor Young also mentions the increasing importance of the electric locomotive. Although this type of traction has not developed sufficiently to permit judgment as to future standards, the writer is prepared to state that the more advanced designs of the electric locomotive show features which fully justify the adoption of the M-loading. The new Norfolk and Western type of electric locomotive has eight axle loads of 70 250 lb. each, in two closely spaced groups, and, therefore, resembles a Mallet wheel diagram. The writer has calculated its stresses and finds that it is safely and economically represented by M-52.

Of the alternative forms of the proposed loading, Professor Young favors the loading formula (M-Loading No. 3) as most direct and scientific, and therein agrees with the preference of the writer. It does not seem expedient at this time, however, to introduce such an innovation into general specifications.

Mr. Godfrey endorses the writer's conclusion that, for the heaviest locomotives and train loads, the Cooper loading does not give consistent stresses nor economic designs. This, however, Mr. Godfrey does not regard as a

sufficient reason for making a change. In the writer's opinion, Mr. Godfrey's arguments involve the fallacy of giving undue prominence to the existing ratings of old bridges, and of under-rating the importance of the proper design of new bridges. Sooner or later, all capacity ratings will have to be reviewed or revised for loading development, and, eventually, all bridges will have to be rebuilt. It appears, therefore, to be a short-sighted policy to perpetuate an old loading system which, it is admitted, does not correspond with the latest in modern engine construction, in order to save the temporary (and over-estimated) trouble of making a change. Moreover, even for the rating of bridges, the M-system will be found to be a time saver, for it will facilitate comparison of rated capacities with actual modern loadings.

Apparently forgetting his own arguments against a change of loading standard, Mr. Godfrey proposes to modify the Cooper loading in order to correct its shortcomings. This proposal would not obviate the need of revising existing bridge ratings, the difficulty of which Mr. Godfrey has cited as his principal objection to a change of specification.

The two modifications of the Cooper loading proposed by Mr. Godfrey are a reduction of the uniform train load behind the locomotive, and an increase in weight of the alternative axle concentrations; the proposed M-loading combines these features in a much simpler diagram, and gives the desired results without the use of any alternative loads.

Mr. Robinson expresses a strong preference for the Cooper loading. He cites, as his authority, the report of the Sub-Committee of the American Railway Engineering Association in preparing the Specifications of 1920.* The writer, in his investigation, used the same locomotives that were considered in that report, and from them derived the proposed M-loadings. It appears inconsistent to cite that report as an authority and, at the same time, to criticize the writer's loading assumptions.

Mr. Robinson contends that not many Mallet locomotives will be built in the future, because the Santa Fé and Mikado types are more efficient. According to Mr. Bland's findings, the M-loading fits the Mikado stresses consistently, and, as shown by Plate XIV, the M-loading fits the stress-producing effects of locomotives of the Santa Fé type much better than the Cooper loading. Mr. Robinson admits that it may prove necessary later to revise the Cooper loading; but, if a change is anticipated, there is no time like the present for making it.

Mr. Robinson also argues that M-60 is too heavy for locomotives in general use. If that is true, the railway engineer can specify M-50 instead. The essential point is not the index number, but the adoption of a correct type of loading to produce properly balanced designs for anticipated development.

Mr. Moore endorses the writer's investigations and conclusions. He makes the important point that any change which better meets the tendencies of locomotive design is an advance.

He declares his preference for M-Loading No. 1 (the typical engine diagram), as it permits stresses to be checked by judgment. The requirements

* *Bulletin*, Am. Ry. Eng. Assoc., January, 1920, p. 511.

of the lighter lines, he points out, can be met by reducing M-60 to a lower index.

Mr. Moore also raises the interesting question of electric locomotives. He mentions the Norfolk and Western freight locomotive that has four axles of 70 250 lb. each, concentrated in a distance of 16 ft. 6 in., with another similar series of loads 22 ft. away.* The writer agrees with Mr. Moore that the stress-producing effects of this locomotive are nearly as great as those of the series of steam locomotives used in deriving the composite. Calculations show that this locomotive, followed by 210 000-lb. cars, is closely and consistently represented by the M-52 loading. (In the Cooper system, the equivalent is E-67 at short spans and E-50 at long spans, a variation of 34 per cent.)

Mr. Moore believes that increase in length of locomotive with new wheel arrangements is more probable in future developments than further intensification of axle concentrations. That would be another argument for the M-loading, as it provides for more axle loads per locomotive than the Cooper loading.

Mr. Moore makes one suggestion open to question, namely, that the uniform train load behind the locomotive should be kept constant. There are practical obstacles to such a specification. The writer has chosen a middle ground between this suggestion to keep the train load constant and the contentions of those who believe that future train loads will increase more rapidly than locomotive loads. Economic considerations would indicate that Mr. Moore's prediction is the more likely. The middle course adopted by the writer follows the line indicated by past experience, and is dictated by practical expediency.

Mr. Moore concludes that the proposed loadings are progressive and will be justified by future locomotive developments; and he expresses his conviction that the M-loading will soon be generally adopted.

Professor Wing devotes his discussion principally to a consideration of the choice of form of loading specification. He prefers the actual heavy engine diagrams for rating the capacity of existing bridges, and the typical engine diagram (M-Loading No. 1) for the design of new bridges. For the rating of existing bridges, he will find that it will save time to determine and use the M-equivalent of the governing locomotives on any line, similar to the series of M-equivalents established by Mr. Bland for the different governing locomotives on the Pennsylvania Lines.

Mr. Stewart regards the writer's proposals as extreme, because they are based on maximum instead of average locomotives. This point has already been discussed at length, and the writer's position that a progressive loading system should anticipate future development really agrees with Mr. Stewart's admission that:

"As the tendency has been * * * for the weight of rolling stock to increase slowly, the standard loading should tend to be more nearly normal to the heavier rather than to the lighter existing or probable locomotives."

The writer does not agree with Mr. Stewart's statement that the M-loading cannot be reduced to fit the lighter classes of locomotives. Independent

* *Engineering News-Record*, September 14, 1922, p. 437.

calculations made by the writer and by Mr. Bland, of the Pennsylvania System, show that the M-system furnishes consistent ratings even for Consolidation locomotives. The M-loading is as good as the Cooper system (and simpler) for the lighter locomotive types, and it is better than the Cooper system for the heavier types.

Professor Jacoby endorses the writer's comparisons between the composite of the heavy modern loadings and the Cooper standard now in use. He points out that it is an easy matter for any railroad to make its own comparison of its governing locomotives with the M-standard, and to determine how closely a reduction of index from M-60 would fit the results. He recommends the M-Loading No. 1 (the typical engine diagram) as the most expedient and practical.

Mr. Fowler endorses the writer's position that the Cooper system is badly out of date and out of time with modern bridge engineering, and that a composite loading is the correct solution of the problem. He also agrees with the writer that the Cooper standard perpetuates the incorrect ratio of train load to locomotive load, and cites, as an instance, the fact that the weight of the train behind the heaviest locomotive on the Michigan Central Railroad is only 4 000 lb. per lin. ft.

Mr. Loweth declares himself in sympathy with the movement to simplify and make more practical the typical engine and train loadings used for proportioning railroad bridges. He cites the repeated past experience of designing bridges for the heaviest locomotives known with a margin for possible increase, only to find the assumed loading exceeded by heavier locomotives before the bridge was completed. Surely, this is a sufficient answer to those who criticize the proposed M-loading as being based on locomotives heavier than the average.

Mr. Loweth's statement that electric locomotives produce less impact is a consideration which, in the writer's opinion, should be covered in the impact formula and not in the loading specification. He suggests further that electric locomotives will be less frequently double-headed than steam locomotives, which is an argument in favor of the M-engine diagram, as that diagram consists of a single-headed locomotive.

Mr. Modjeski endorses the writer's conclusion that the Cooper standard loading does not properly represent modern loading conditions. He also suggests modifying the Cooper loading and using E-73 + 6 000 instead of M-60, which suggestion has already been discussed.

Mr. Modjeski indicates a perference for the second alternative, namely, a uniform load with floating concentrations (M-Loading No. 2).

Mr. Turner presents a theoretical analysis of impact, particularly as affected by speed. From this, he concludes that the impact for E-60 loading at passenger train speed would be nearly equal to that of an E-75 loading at freight train speed. Similar relations can be established, of course, between different indices of the M-system of loads, but the writer does not see how they affect the choice as between the Class-E and the Class-M loadings. The proper place to cover considerations of impact is in the specification for

impact, not in the specification for loads. If it is Mr. Turner's idea that a loading specification should be based on passenger locomotives and not on freight locomotives, the writer does not believe that the Profession would share such a view.

In closing, the writer wishes to state that, after reviewing the discussions, he is confirmed in his conclusions that the Cooper engine diagram does not properly represent modern loading conditions; and he submits the M-loading (Fig. 19) as the final result of his studies to determine the best possible loading specification to meet present-day and future loading conditions.
